SUMMARY

Currently there is no general approach for achieving specific optogenetic control of genetically defined cell types in rats, which provide a powerful experimental system for numerous established neurophysiological and behavioral paradigms. To overcome this challenge we have generated genetically restricted recombinase-driver rat lines suitable for driving gene expression in specific cell types, expressing Cre recombinase under the control of large genomic regulatory regions (200–300 kb). Multiple tyrosine hydroxylase (*Th*::Cre and choline acetyltransferase (*Chat*::Cre lines were produced that exhibited specific opsin expression in targeted cell types. We additionally developed methods for utilizing optogenetic tools in freely moving rats and leveraged these technologies to clarify the causal relationship between dopamine (DA) neuron firing and positive reinforcement, observing that optical stimulation of DA neurons in the ventral tegmental area (VTA) of *Th*::Cre rats is sufficient to support vigorous intracranial self-stimulation (ICSS). These studies complement existing targeting approaches by extending the generalizability of optogenetics to traditionally non-genetically-tractable but vital animal models.

INTRODUCTION

While genetically modified mice have enabled substantial advances in neuroscience and have made possible new approaches for circuit analysis with optogenetics (Tsai et al., 2009; Gradinaru et al., 2009; Lobo et al., 2010; Kravitz et al., 2010; Witten et al., 2010; Tye et al., 2011), a generalizable approach for optogenetic targeting of genetically defined cell types in rats has proven to be elusive. This technological limitation is particularly important to address given that the substantial and flexible behavioral repertoire of rats makes these animals the preferred rodent model in many fields of neuroscience experimentation, and a wide variety of behavioral tasks have been optimized for this species (Bari et al., 2008; Chudasama and Robbins, 2004; Uchida and Mainen, 2003; Otazu et al., 2009; Pontecorvo et al., 1996; Vanderschuren and Everitt, 2004; Phillips et al., 2003; Pedersen et al., 1982). Furthermore, rats represent an essential system for in vivo electrophysiology, with dimensions that enable accommodation of the substantial numbers of electrodes required to obtain simultaneous data from large neuronal populations (Wilson and McNaughton, 1993; Royer et al., 2010; Buzsáki et al., 1989; Gutierrez et al., 2010; Colgin et al., 2009; Jog et al., 2002; Berke et al., 2009). Therefore, the ability to utilize population-selective genetically targeted optogenetic tools in the rat would be a valuable technical advance.

Most efforts to target genetically defined neurons in rats have relied on viral strategies, but given the paucity of compact and well-characterized promoters, this approach has only rarely led

to highly specific targeting (Lee et al., 2010; Lawlor et al., 2009; Nathanson et al., 2009). Alternatively, transgenic rat lines can be generated to enable use of specific larger promoter-enhancer regions (Filipiak and Saunders, 2006), but for expression of opsins in the brain this approach suffers from two serious limitations. First, this method is low throughput and not well suited for keeping pace with the rapidly advancing opsin toolbox (requiring specific design, line generation, multigenerational breeding, and testing of each individual rat line for a particular opsin gene). Second, this approach is inconsistent with straightforward optogenetic control of single or multiple spatially distinct populations; in fact, a breakdown in specificity for control of cells or projections within a particular illuminated brain region arises because opsins traffic efficiently down axons (Gradinaru et al., 2010) and incoming afferents from other brain regions that are photosensitive will confound experiments by exhibiting optical sensitivity alongside local cell populations. For example, in a rat line expressing opsins in all catecholamine neurons, illumination of the ventral tegmental area (VTA) would activate both dopamine (DA) cell bodies in the VTA and noradrenergic projections to the VTA originating from cells in the locus coeruleus.

Here, we explore an alternative approach addressing all of the above fundamental limitations, instead generating a panel of the first characterized and specific transgenic recombinase-driver rat lines, with regulatory information contained in 200–300 kb of DNA upstream and downstream of the target genes (an approach that has achieved considerable success in mice; Gong et al., 2007). In these rats, large amounts of regulatory information are packaged in bacterial artificial chromosomes (BACs), with packaging capability that can accommodate regulatory sequences dispersed across large regions of the genome. We then apply these resources in combination with a panel of novel rat-specific optogenetic behavioral approaches and spatially specific injection of Cre-dependent opsin-expressing viral vectors to explore the causal relationship between DA neuron firing and positive reinforcement during optical intracranial self-stimulation (ICSS) in freely moving rats.

Over the course of the last half-century, electrical ICSS has emerged as a powerful approach to identify brain areas that serve as positive reinforcement sites (Olds and Milner, 1954; Olds, 1963; Corbett and Wise, 1980), and the bulk of the relevant experiments have been conducted in rats. An extensive literature suggests that DA neurons play an important role in electrical ICSS, as altering levels of DA or lesioning DA neurons dramatically affects ICSS thresholds (Fibiger et al., 1987; German and Bowden, 1974; Fouriez and Wise, 1976; Mogenson et al., 1979; Wise and Rompré, 1989) and effective sites for ICSS, including the medial forebrain bundle, closely parallel the anatomical location of DA neurons or their broad projections (Corbett and Wise, 1980). However, several studies have suggested that powerful ICSS sites may have a nondopaminergic component, or perhaps not even require DA neurons at all. Robust ICSS has been demonstrated behaviorally without metabolic activation of major dopaminergic projection targets (Gallistel et al., 1985), and rats with near-complete lesions of the DA system show reduced but still significant ICSS behavior (Fibiger et al., 1987). Additionally, the electrophysiological prop-

erties of axons thought to be necessary for sustaining ICSS were shown to be inconsistent with the conduction velocity of DA axons (Bielajew and Shizgal, 1986). Further, studies employing *in vivo* voltammetry during ICSS have found that DA release in the nucleus accumbens (NAc), a major efferent target of DA neurons, is only rarely observed in well-trained animals (Owesson-White et al., 2008; Garriss et al., 1999). Finally, a recent optogenetic study in mice found that DA neuron stimulation by itself was not sufficient for the acquisition of ICSS (Adamantidis et al., 2011).

The challenge in linking DA neuron activation to ICSS may be rooted in the complexity and heterogeneity of the VTA, coupled with ambiguities inherent to electrical stimulation. Fewer than 60% of neurons in the rat VTA are dopaminergic (Margolis et al., 2006; Fields et al., 2007; Nair-Roberts et al., 2008; Swanson, 1982). The sizeable population of GABAergic and to a lesser extent glutamatergic neurons that constitute the remainder send extensive efferent projections both within and outside of the VTA (Dobi et al., 2010; Yamaguchi et al., 2011). An additional concern arises from recent imaging experiments demonstrating that electrical stimulation activates a sparse and scattered neural population with a spatial distribution that is difficult to predict (Histed et al., 2009). This issue is particularly significant given the wide array of brain areas that support electrical ICSS (Wise, 1996; German and Bowden, 1974; Olds and Olds, 1963). Electrical stimulation of the VTA therefore undoubtedly activates a complex and heterogeneous circuitry; to circumvent this issue we applied one of the novel recombinase driver rat lines developed and reported here to test the hypotheses that direct activation of VTA DA neurons will be sufficient to (1) acquire and (2) sustain ICSS in freely moving rats.

RESULTS

Specific Targeting of Dopaminergic and Noradrenergic Neurons in *Th::Cre* Rats

We first generated multiple BAC transgenic rat lines expressing Cre recombinase in tyrosine hydroxylase (TH) neurons (*Experimental Procedures*) and tested the specificity and potency of these lines for potential optogenetic experiments (*Figures 1–3*). Injection of a Cre-dependent virus in dopaminergic (VTA or substantia nigra pars compacta, SN) or noradrenergic (locus coeruleus, LC) structures in *Th::Cre* rat lines resulted in highly specific channelrhodopsin-2 (ChR2) expression in catecholamine neurons (*Figures 1A–1D*). In the case of the VTA and SN injection, opsin expression was confined to TH⁺ cell bodies and processes (*Figures 1A–1C*) and to projections of these cells within known target structures (e.g., ventral and dorsal striatum, *Figure 1C*, bottom). Similarly, with the LC as an injection target, opsin expression was confined to the TH⁺ LC cell bodies and their processes; *Figure 1D*). Additionally, to confirm that the VTA and LC could be targeted independently in this rat line (a potential concern because both areas express TH and therefore Cre), virus was injected in the VTA and lack of expression was demonstrated in the LC (*Figure S1*, available online).

Importantly, *Th::Cre* sublines from different founders varied quantitatively in specificity and strength of expression

Figure 1. Specific ChR2-YFP Expression in the VTA, SN, and LC of *Th::Cre* Rats

(A) Quantification of ChR2-YFP expression profile in several *Th::Cre* sublines (VTA: line 2.1, $n = 113$, line 3.1, $n = 150$, line 3.2, $n = 190$, line 3.5, $n = 122$, line 4.4, $n = 126$; SN: line 3.1, $n = 86$; LC: line 3.1, $n = 63$ —where n refers to the number of counted cells that expressed either YFP or TH). Error bars represent SEM.

(B) High-magnification view of ChR2-YFP expression and DAPI staining in TH⁺ VTA cell bodies after injection of Cre-dependent virus in the VTA of a *Th::Cre* rat.

(C) TH staining and ChR2-YFP expression in coronal slices display colocalization in cell bodies (top: VTA and SN) and efferents in the ventral and dorsal striatum (bottom).

(D) Colocalization of TH staining and ChR2-YFP expression in the LC after injection of Cre-dependent virus in a *Th::Cre* rat.

We performed a systematic in vitro electrophysiological study of the cellular and optogenetic properties of ChR2-YFP-expressing VTA neurons in *Th::Cre* rats, along with a comparison of the same properties of neurons in *Th::Cre* littermates injected with a control virus that expressed only YFP. Figure 2A shows a sample trace from a ChR2-expressing *Th::Cre* neuron in response to current injection steps, demonstrating the classical “sag” response induced by the hyperpolarizing pulse, the result of a hyperpolarization-activated cation current (I_h) that is present in many TH⁺ VTA neurons (Margolis et al., 2006; Lammel et al., 2008, 2011; Neuhoff et al., 2002). Given that the VTA TH⁺ neurons are heterogeneous and do not all express a prominent I_h (Lammel et al., 2008, 2011), in addition to analyzing light responses and intrinsic properties of neurons with a prominent I_h current ($I_{h/large}$ neurons), we have also included in this analysis cells without a prominent I_h ($I_{h/small}$ neurons), in either case comparing the properties of neurons that express ChR2-YFP to neurons that express YFP only.

Continuous blue light elicited large inward currents (peak photocurrent: -2950 ± 1574 pA for $I_{h/large}$ neurons, steady-state photocurrent: -756.5 ± 225.5 pA; $n = 7$ $I_{h/large}$ neurons, Figure 2B), and optical stimulation trains produced neural responses that were similar to those evoked by electrical stimulation in both ChR2-expressing or YFP-only-expressing neurons (Figure 2C for pulse trains, Figure S2D for individual waveforms); notably, the amplitude of both optically and electrically evoked spike trains attenuated during the course of the pulse train. *Th::Cre* ChR2-expressing neurons reliably responded to light-induced spike trains over a range of frequencies from 5 to 40 Hz (Figure 2D for $I_{h/large}$ neurons, Figure S2B for $I_{h/small}$ neurons). Multiple spikes in response to a single light pulse were never observed during the presentation of pulse trains under these expression, illumination, and opsin (ChR2) conditions. We also confirmed that light stimulation at various frequencies (5 to 40 Hz) failed

(Figure 1A). The offspring of founder 3 (line 3.1, 3.2, and 3.5) were used in all experiments in this paper, chosen for the highest specificity. For example, in the VTA of line 3.5, $99\% \pm 1\%$ of neurons that expressed ChR2-YFP also expressed TH (a measure of specificity), while $61\% \pm 4\%$ of neurons that expressed TH also expressed ChR2-YFP (a measure of the proportion of targeted neurons that expressed the transgene). In the SN of line 3.1, $84\% \pm 4\%$ of neurons that expressed ChR2-YFP also expressed TH, while $77\% \pm 5\%$ of neurons that expressed TH also expressed ChR2-YFP. In the LC of line 3.1, $97\% \pm 1\%$ of neurons that expressed ChR2-YFP also expressed TH, while $72\% \pm 6\%$ of neurons that expressed TH also expressed ChR2-YFP ($n = 122$ for VTA, $n = 86$ for SN, $n = 63$ for LC, where n refers to counted cells; Figure 1A). To further characterize these lines, we quantified the copy number of *Cre* in *Th::Cre* rats with digital PCR (Supplemental Experimental Procedures). Across multiple sublines (*Th::Cre* 3.1, 3.5, and 4.4), we observed a single copy number of *Cre* in the genome (Table S1).

Figure 2. In Vitro and In Vivo Physiology of Optical Responses in VTA DA Neurons in *Th::Cre* Rats

(A) Example traces from a ChR2-expressing *Th::Cre* neuron in response to intracellular current injections (V_m : -43 mV, 50 pA current steps beginning at -500 pA).

(B) Continuous blue light (470 nm) evokes large (>500 pA) inward currents in ChR2-expressing *Th::Cre* neurons. Inset: summary graph of population data for photocurrent properties ($n = 7$).

(C) Representative responses to 20 Hz optical or electrical stimulation trains in ChR2-expressing and YFP-only-expressing *Th::Cre* neurons. Spike size and shape are comparable to those previously reported for these cells.

(D) Left: ChR2-expressing *Th::Cre* neurons are able to reliably follow light-evoked pulse trains over a range of frequencies. Right: summary data for spike fidelity (%successful spikes in 40 light flashes) in ChR2-expressing *Th::Cre* neurons ($n = 7$; in A–D data are from $I_{h/large}$ ChR2-YFP expressing cells). Error bars represent SEM.

(E) Optically evoked time-locked multiunit neural activity recorded with an optrode in vivo in the VTA of anesthetized *Th::Cre* rats injected with Cre-dependent ChR2. Top: 20 Hz, 20 pulses, 5 ms pulse duration, 473 nm. Bottom: same recording site and photostimulation parameters but longer stimulation duration (100 pulses). Horizontal blue lines represent time course of optical stimulation.

to evoke neural responses in YFP-only-expressing neurons (Figure S2C).

Additionally, we compared the intrinsic properties of ChR2-YFP- and YFP-only-expressing neurons from *Th::Cre* rats to control for the possibility that these properties may have been altered by ChR2 expression. We found that expression of ChR2 did not significantly alter the initial resting membrane potential (-42.6 ± 1.2 mV for ChR2 $I_{h/large}$ cells versus -45.6 ± 0.5 mV for YFP $I_{h/large}$ cells; -45.4 ± 0.8 mV for ChR2 $I_{h/small}$ cells versus -44.1 ± 5.6 mV for YFP $I_{h/small}$ cells), magnitude of the I_h current (486.0 ± 161.1 pA for ChR2 $I_{h/large}$ cells versus 507.2 ± 295.5 pA for YFP $I_{h/large}$ cells; 78.5 ± 36.0 pA for ChR2 $I_{h/small}$ cells versus 52.6 ± 21.8 pA for YFP $I_{h/small}$ cells), input resistance (502.0 ± 72.6 M Ω for ChR2 $I_{h/large}$ cells versus 616.3 ± 41.2 M Ω for YFP $I_{h/large}$ cells; 474.1 ± 56.6 M Ω for ChR2 $I_{h/small}$ cells versus 465.1 ± 109.4 M Ω for YFP $I_{h/small}$ cells), and action potential threshold (-27.6 ± 12.9 mV for ChR2 $I_{h/large}$ cells versus -30.0 ± 4.35 mV for YFP $I_{h/large}$ cells; -25.4 ± 7.4 mV for ChR2 $I_{h/small}$ cells versus -27.0 ± 7.1 mV for YFP $I_{h/small}$ cells) as compared to YFP-only-expressing neurons (Figure S2A, $n = 7$ for ChR2 $I_{h/large}$ cells, $n = 3$ for YFP $I_{h/large}$ cells, $n = 4$ for ChR2 $I_{h/small}$ cells, $n = 5$ for YFP $I_{h/small}$ cells, $p > 0.05$ for all comparisons, two-tailed t test).

To complement the in vitro recordings and more fully characterize these new optogenetic tools, we validated tool functionality with electrophysiology in vivo as well. Optical stimulation of ChR2-expressing *Th::Cre* neurons resulted in reliable light-evoked neural activity in vivo assessed with optrodes; in particular, the targeted population was able to follow 20 Hz stimulation with a steady-state response level that was stable after ten light pulses and extending to at least 100 pulses (Figure 2E).

Next, to confirm that light-evoked neural activity resulted in neurotransmitter release, we used fast-scan cyclic voltammetry to measure DA release in acute brain slices of the NAc of *Th::Cre* rats that had been injected in the VTA with a Cre-dependent ChR2-expressing virus (Figure 3). One second of 20 Hz optical stimulation resulted in phasic transients with the characteristic DA current/voltage relationship (example site, Figure 3A); across the population, mean amplitude of the transient was 0.33 ± 0.1 μ M ($n = 17$ recording sites). The amplitude of the NAc DA transient increased monotonically but not linearly with the number of 20 Hz stimulation pulses; this quantitative relationship is illustrated in Figure 3B. Light-evoked phasic DA release was TTX dependent (Figure 3C), implicating presynaptic activation of voltage-gated Na^+ channels in optically evoked DA release.

Specific Targeting of Cholinergic Neurons in *Chat::Cre* Rats

A separate set of Cre driver rat lines was also generated, in this case leading to specific optogenetic targeting of cholinergic neurons and demonstrating the versatility of this approach (Figure 4). In the medial septum of *Chat::Cre* line 5.2, $92\% \pm 2\%$ of neurons that expressed YFP also expressed ChAT, and $51\% \pm 4\%$ of neurons that expressed ChAT also expressed YFP ($n = 118$); in the nucleus basalis, $98\% \pm 1\%$ of neurons that expressed YFP also expressed ChAT, and $88\% \pm 3\%$ of neurons that expressed ChAT also expressed YFP ($n = 173$).

Figure 3. Voltammetric Measurements of Optically Evoked DA Release In Vitro in the Nucleus Accumbens of *Th::Cre* Rats Expressing Cre-Dependent ChR2 in the VTA

(A) Time course of DA release at a sample site (20 pulses). (B) Time course of DA release for various numbers of pulses at a sample site (top); peak DA release as a function of the number of pulses across the population (bottom, $n = 17$). Error bars represent SEM.

(C) Bath application of TTX (1 μ M) blocked optically evoked DA release (left: before TTX, right: after TTX; 100 pulses). Horizontal blue lines represent time course of optical stimulation. In (A)–(C), optical stimulation parameters: 20 Hz, 5 ms pulse duration, 473 nm.

spiking in surrounding cells of the nucleus basalis, revealing not only light-driven spiking but also potent light-driven influences on neural circuit function in this Cre driver rat line (Figure 4F).

Methods for Optogenetic Stimulation in Freely Moving Rats

In order to capitalize on these new reagents, we developed a system for optogenetic stimulation in freely behaving rats (Figure 5). The essential components of this system are (1) an implantable optical fiber to reduce fiber breakages that result from repeatedly connecting to a light source over multiple behavioral sessions, (2) a secure connection between the implanted fiber and optical cable, (3) a protective spring encasing the optical patch cable to improve durability, (4) a counterbalanced lever arm to reduce tension associated with the attached cable, and (5) an optical commutator to allow the optical cable attached to the rat to rotate freely during behavioral sessions. The design

and use of these rat-optimized optogenetic tools are described in the [Experimental Procedures](#).

neurons); in the NAc, $97\% \pm 3\%$ of neurons that expressed YFP also expressed ChAT, and $90\% \pm 5\%$ of neurons that expressed ChAT also expressed YFP ($n = 40$ neurons) (Figures 4A and 4B). A quantification of copy number in the *Chat::Cre* lines revealed an estimated copy number of 6 (Table S1), which may contribute to the high proportion of ChAT neurons that expressed YFP in the nucleus basalis and the NAc.

Since direct optrode recording of ChAT neurons in vivo is much more challenging due to population sparsity (in contrast to the relatively abundant TH⁺ neurons in the VTA; Figure 2E), we confirmed light-evoked neural activation with acute slice patch-clamp recordings of neurons in the nucleus basalis that expressed ChR2-YFP (Figures 4C and 4D). This approach revealed that optical stimulation of ChAT cells led to large inward currents (>500 pA) as well as robust light-evoked action potentials across a broad frequency range (5–40 Hz, Figure 4E). Moreover, we were able to employ optrode recordings in vivo to assess the effect of the directly activated ChAT cells on surrounding circuitry; when these cells were optically stimulated in vivo, we observed potent inhibition of spontaneous

and use of these rat-optimized optogenetic tools are described in the [Experimental Procedures](#).

Application to Dopamine-Mediated Positive Reinforcement

Finally, we applied this technology to map quantitative relationships between activation of VTA DA neurons in rats and self-stimulation behavior. *Th::Cre* rats and their wild-type littermates received identical injections of Cre-dependent ChR2 virus in the VTA, as well as optical fiber implants targeted dorsal to this structure (Figure 6A; see Figure S3 for placement summary and fluorescence images). All rats were given the opportunity to respond freely at two identical nosepoke ports. A response at the active port resulted in a 1 s train of light pulses (20 Hz, 20 pulses, 5 ms pulse duration) delivered on a fixed-ratio 1 (FR1) schedule, while responses at the inactive port were without consequence. *Th::Cre* rats made significantly more responses at the active port relative to the inactive port on all 4 days of training (Figures 6B, 2-tailed Wilcoxon signed-rank test with Bonferroni correction, $p < 0.05$ on days 1–4; see also Figure 6C

Figure 4. Specificity and Functionality of *Chat::Cre* Rats

(A) Quantification of YFP expression profile in *Chat::Cre* sublines in the medial septum (MS), nucleus basalis (NB), and nucleus accumbens (NAc) after injection of a Cre-dependent virus. Error bars represent SEM.

(B) Colocalization of ChAT staining and YFP expression in the MS (top), NB (middle), and NAc (bottom).

(C) Membrane potential changes induced by current injection in a ChR2-YFP expressing ChAT neuron. VM = -53mV. Current steps: -100, +50 pA. (D) Voltage-clamp recording of a neuron expressing ChR2-YFP in slice showing inward current in response to blue light (1 s constant illumination, 470 nm).

(E) Current-clamp recording of light-evoked action potentials in a ChAT neuron expressing ChR2-YFP in slice in response to several stimulation frequencies (470 nm, 2 ms pulse duration, 40 pulses).

(F) In vivo inhibition of multiunit activity in response to optical activation of ChAT cells in the nucleus basalis with ChR2. Top: example voltage trace. Middle: raster plot from eight repetitions. Bottom: time average and SEM (from raster plot). (10 Hz, 10 ms pulse duration, 5 pulses, 473 nm.)

for cumulative active nosepoke responding across all days of training for a representative rat), indicating rapid acquisition of DA ICSS. By the third and fourth training day, *Th::Cre*⁺ rats performed more than 4,000 nosepokes on average at the active port, compared to fewer than 100 at the inactive port (Figure 6B). Variability in the vigor of responding between subjects (Figure 6D) could be explained by differences in the strength of virus expression directly beneath the implanted optical fiber tip (t test, $p < 0.05$, $r^2 = 0.55$; see Figures S3A–S3C for placement summary and fluorescence quantification). Additionally, *Th::Cre*[−] rats made significantly fewer nosepokes at the active port than *Th::Cre*⁺ rats on all 4 days (2-tailed Mann-Whitney test with Bonferroni correction, $p < 0.05$ on day 1, $p < 0.005$ on

days 2–4). Notably, responding of *Th::Cre*[−] rats at the active port was indistinguishable from responding at the inactive port (two-tailed Wilcoxon signed-rank test with Bonferroni correction; $p > 0.05$), indicating that active port responses in *Th::Cre*[−] rats were not altered by optical stimulation.

We then systematically varied the duration of optical stimulation that was provided for each single active nosepoke response in order to investigate the relationship between the magnitude of dopaminergic neuron activation and the vigor of behavioral responding (“duration-response test”). We chose to vary stimulation duration, having already established that altering this parameter results in corresponding changes in evoked DA transients in vitro (Figure 3B). Further, varying this parameter allowed

Figure 5. Rat-Optimized Integration of Optogenetic Photostimulation with Freely Moving Behavior in an Operant Conditioning Chamber

(A) Schematic of the behavioral set-up, which was optimized to facilitate freely moving behavior along with photostimulation (while minimizing the chance of fiber breakage or disconnection). An optical fiber in a metal ferrule was surgically implanted over the targeted brain area (1) and connected with a ceramic sleeve (2) to a patch cable encased in a protective spring (3). A counterbalanced lever arm compensated for accumulation of slack in the patch cable during rearing (4), and an optical commutator (5) enabled the rat to rotate freely in the chamber.

(B) A close-up view of the implantable fiber in the metal ferrule (1), the ceramic sleeve (2), and the patch cord encased in the protective spring (3).

us to confirm that later spikes in a stimulation train are still propagated faithfully to generate DA release in the behaving rat (in agreement with our *in vitro* confirmation, Figure 3B). The rate of responding of *Th::Cre+* rats at the active nosepoke port depended powerfully on the duration of stimulation received (Figure 6E, Kruskal-Wallis test, $p < 0.0001$). Response rate increased more than threefold as the duration of the stimulation train increased from 5 ms to 1 s and saturated for durations above 1 s. This saturation could not be explained by a ceiling effect on the number of reinforcers that could be earned, since even for the longest stimulation train durations, rats earned on average less than 50% of the possible available optical stimulation trains (Figure 6E, inset).

We further applied two classical behavioral tests to confirm that rats were responding to obtain response-contingent optical stimulation, rather than showing nonspecific increases in arousal and activity subsequent to DA neuron activation. First, we tested the effect of discontinuing stimulation during the middle of a self-stimulation session. Rats were allowed to respond over 30 min for 1 s stimulation trains (20 Hz, 20 pulses, 5 ms pulse duration; “maintenance”). Subsequently, stimulation was discontinued and responses at the active port had no effect (“extinction”). After a further 30 min had elapsed, brief “priming” stimulation trains were delivered to indicate to the rat that stimulation was once again available (“reacquisition”). We found that *Th::Cre+* rats rapidly extinguished and then reacquired responding for DA ICSS, performing significantly fewer active nosepokes during extinction as compared to both maintenance and reacquisition (two-tailed Wilcoxon signed-rank test; $p < 0.01$ for maintenance versus extinction, $p < 0.05$ for extinction versus reacquisition, Figures 6F and 6G). The extinction of active responding was rapid; within 5 min after extinction onset, rats had decreased their average rate of responding at the active nosepoke to less than 10% of the rate sustained during maintenance. Importantly, by the last 5 min of the extinction phase *Th::Cre+* rats no longer responded preferentially at the active nosepoke (Figure 6H), instead responding at equivalently low levels at both active and inactive nosepoke ports.

Next, we asked whether the contingency between behavioral responses and optical stimulation was required to sustain responding. Rats were allowed to respond for stimulation over 30 min (“maintenance”), followed by a period of contingency degradation (“CD”) during which stimulation trains were delivered pseudorandomly at intervals matched to the average rate at which they were earned by each rat during FR1 responding in a previous session. Rats could continue to respond at the active port during this phase, but the delivery of stimulation trains occurred independently of these responses. After 30 min had passed, noncontingent stimulation ceased and reinforcement was once again made contingent on responses in the active port (“reacquisition”). We found that *Th::Cre+* rats were sensitive to degradation of the contingency between response and reinforcement, as they performed significantly fewer active nosepokes during CD than they had during maintenance (two-tailed Wilcoxon signed-rank test, $p < 0.01$; Figures 6I and 6J) despite the fact that the number of stimulation trains delivered did not differ across the two epochs (two-tailed Wilcoxon signed-rank test, $p > 0.05$, Figure 6J). Interestingly, by the last 5 min of the

CD phase *Th::Cre+* rats still showed a small but significant preference for responding at the active nosepoke (Figure 6K). Additionally, on average rats increased responding at the active port during reacquisition, although when summed across the 30 min epoch this change was not statistically significant (two-tailed Wilcoxon signed-rank test, $p > 0.05$; Figure 6J). Together, the extinction and contingency degradation manipulations demonstrate that the robust maintenance of *Th::Cre+* rat responding at the active port arises from response-contingent optical stimulation of DA neurons.

DISCUSSION

Here, we introduce a panel of the first genetically targeted and validated recombinase-driver rat lines and demonstrate the utility of these lines as versatile and effective tools to target opsins to genetically defined cell types in this essential animal model. Most efforts to target genetically defined subpopulations of neurons in rats have relied on viral strategies (Lawlor et al., 2009; Lee et al., 2010), but since compact promoters are rare and viral vectors have limited packing capacity, published attempts often result in only partial specificity for the targeted cell type (Tan et al., 2008; Nathanson et al., 2009; Wang et al., 1999). In contrast, we found that BAC Cre transgenic rats offer an attractive alternative for precise optogenetic targeting. We were able to achieve 98% and 84% specific opsin expression in DA neurons of the VTA and SN, respectively, as well as 97% opsin specificity in noradrenergic neurons of the LC in *Th::Cre* rats. We also observed 92%, 98%, and 97% specificity in cholinergic neurons of the medial septum, nucleus basalis, and NAc, respectively, in *Chat::Cre* rats.

These lines thus offer a powerful means to selectively target dopaminergic, noradrenergic, and cholinergic neurons in rats, providing long-sought experimental control of neuronal populations that are likely to influence a wide variety of neural and behavioral functions (Changeux, 2010; Surmeier et al., 2009; Shen et al., 2008; Gerfen and Surmeier, 2011; Nader and LeDoux, 1999; Montague et al., 2004) in this important animal system. When combined with optogenetics, these tools now enable selective control of neuromodulatory function with exceptional temporal precision in genetically defined subpopulations and their projections, and we expect this approach to be readily generalizable to other cell types in rats. This approach capitalizes on BAC technology that had been developed for the generation of transgenic mice (Gong et al., 2007); coupling these constructs with recent advances in pronuclear injection technology in rats (Filipiak and Saunders, 2006) results in a versatile approach that will enable targeting of a virtually unlimited array of genetically defined cell types of interest. Our success in achieving cell-type-specific expression in rats was fundamentally related to the very large regulatory/promoter element that we employed (the BACs allowed for a regulatory region of 200–300 kb), which contrasts with the much smaller promoter regions that typically can be packaged in viruses (typically 2–5 kb promoter region, depending on the type of virus and the size of the proteins being expressed by the virus). We were able to achieve specificity for both promoters (*Th* and *Chat*), although not all founders generated offspring with highly specific

Figure 6. Optical Stimulation of VTA DA Neurons Supports Robust Self-Stimulation

(A) The VTA was injected with a Cre-dependent ChR2 virus, and an optical fiber was implanted above the VTA.

(B) Nosepokes during 4 days of FR1 training, in which nosepokes at the active port resulted in photostimulation (20 Hz, 20 pulses, 5 ms duration, 473 nm), while nosepokes at the inactive port were without consequence. *Th::Cre+* rats performed significantly more active than inactive nosepokes (two-tailed Wilcoxon signed-rank test with Bonferroni correction; $p < 0.05$ on days 1–4).

(C) Cumulative responding at the active nosepoke port across all 4 days of training for a representative *Th::Cre+* rat.

(D) Cumulative responding at the active nosepoke port on day 4 of FR1 training for all *Th::Cre+* rats. Dark blue: population average; light blue: individual rats.

(E) Normalized nosepoke rate at the active port for *Th::Cre+* rats for duration-response test in which the relationship between stimulation duration and response rate was mapped systematically. Before averaging across rats, the nosepoke rate for each rat was normalized to the maximum rate across all stimulus durations. Response rate depended on stimulation duration (Kruskal-Wallis test, $p < 0.0001$; 20 Hz, 1–100 pulses, 5 ms pulse duration). Inset: percent of the maximum possible stimulation trains earned as a function of stimulus duration for the same data set.

(F) Cumulative responding at the active port for *Th::Cre+* rats for the within-session extinction test during maintenance, extinction and reacquisition.

(G) Quantification of total active nosepoke responses and stimulation trains delivered during maintenance, extinction, and reacquisition. Response rate decreased during extinction and then increased during reacquisition (two-tailed Wilcoxon signed-rank test; $p < 0.01$ for average nosepokes during maintenance versus extinction, $p < 0.05$ for extinction versus reacquisition).

(H) Quantification of responses at the active and inactive nosepoke ports for the last 5 min of maintenance, extinction, and reacquisition. *Th::Cre+* rats responded preferentially at the active nosepoke port at the end of maintenance and reacquisition, but not extinction (two-tailed Wilcoxon signed-rank test; $p < 0.01$).

expression. In fact, only one *Th::Cre* founder (out of seven) and one *Chat::Cre* founder (out of six) resulted in a high (>90%) specificity line. Thus, a primary step in the generation of transgenic rat lines is the extensive characterization required to validate transgene specificity.

We also demonstrated the efficacy of the *Th::Cre* rats for optogenetic experiments. Specifically, we used *Th::Cre* rats to clarify the relationship between DA neuron activation and positive reinforcement and found that brief phasic optical stimulation of dopaminergic VTA neurons was sufficient to drive vigorous ICSS. Electrical ICSS experiments have been difficult to interpret in the context of phasic DA neuron activation since electrical stimulation activates a heterogeneous and complex population of neurons (Margolis et al., 2006; Fields et al., 2007; Dobi et al., 2010; Lammel et al., 2008; Histed et al., 2009; Nair-Roberts et al., 2008; Swanson, 1982) and fails to elicit reliable DA release in well-trained animals (Garris et al., 1999; Owesson-White et al., 2008). Our studies show that phasic DA stimulation can support both the acquisition and the maintenance of instrumental responding, significantly extending the recent finding that optogenetic stimulation of DA neurons can support conditioned place preference (a form of Pavlovian learning; Tsai et al., 2009).

Interestingly, our characterization of DA ICSS reveals that this behavior has much in common with electrical self-stimulation. First, rats rapidly acquire responding, with some rats responding at remarkably high rates. Second, responding scales with the duration of stimulation. Third, responding is extinguished very rapidly upon cessation of stimulation. And fourth, responding requires contingency between response and reinforcement. Although the current results do not preclude an involvement of other nondopaminergic cell types in mediating electrical ICSS, our findings demonstrate that activation of VTA DA neurons is sufficient, and the strong parallels with electrical self-stimulation are consistent with a major role of DA neuron activation in ICSS.

To our knowledge, all previous demonstrations of optogenetic modulation of mammalian behavior have been performed in mice. The larger size of the rat brain provides both advantages and challenges for optogenetic dissection of the neural circuits underlying behavior. The advantage is that a substructure can be targeted in the rat with greater accuracy, while the disadvantage is that more light will be required to activate the entirety of a structure given greater size. Another fundamental and relevant difference between mice and rats is that the same axon tract will extend a significantly greater distance in rats relative to mice. For example, the projection between the VTA and the NAc will be more than twice as long in rats as mice. Since the time it takes an opsin to express in axons tends to increase with the length of the projection, this fact

could greatly affect the utility of rats as a system to optogenetically stimulate terminals rather than cell bodies (an approach to further increase the specificity of cell populations targeted for optogenetic stimulation). A recent finding that rats will perform ICSS to obtain stimulation not only of the DA cell bodies in the VTA, but also of the VTA DA terminals in the NAc (I.W., E.S., P.J., K.D., unpublished data), provides confidence in the utility of the transgenic rats for optogenetic experiments, despite greater size.

In summary, we have developed a panel of transgenic rat lines that enable a wide range of experiments probing the causal role of neuromodulatory cells in neural circuit function and behavior. The size of the rat brain is amenable to in vivo multielectrode recording studies that can now take advantage of the ability to optogenetically perturb activity in these neural populations in concert with recording, with immediate implications for basic and translational neuroscience. Ultimately, the increasingly sophisticated integration of these new reagents with projection-based targeting and the rich repertoire of rat behavior may continue to deepen our understanding of the neural underpinnings of behavior.

EXPERIMENTAL PROCEDURES

BAC Transgenic Rat Production

The *Th::Cre* construct consisted of a *Cre* gene introduced immediately before the ATG of the mouse *TH* gene (BAC address RP23-350E13); the *Chat::Cre* construct consisted of a *Cre* gene introduced immediately before the ATG of the mouse *Chat* gene (BAC address RP23-246B12), as described previously (Gong et al., 2007). The BAC constructs were purified using NucleoBond BAC 100 from ClonTech. Both BAC DNAs were verified by sequencing and by pulse-field electrophoresis of a *Not*I digest. They were then resuspended in microinjection buffer (10 mM Tris-HCl, pH 7.5, 0.1 mM EDTA 100 mM NaCl + 1 × polyamine) at a concentration of 1.0 ng/μl. The constructs were injected into the nucleus of fertilized eggs (derived from mating Long Evans rats) and transferred to pseudopregnant recipients (University of Michigan transgenic core). This procedure resulted in seven *Th::Cre* and six *Chat::Cre* founder lines with transgene incorporation into the genome, as determined by *Cre* genotyping (Supplemental Experimental Procedures).

Of the initial founders, three *Th::Cre* founders and three *Chat::Cre* founders exhibited robust expression of *Cre*-dependent opsin virus in the VTA or MS, respectively. The breeding procedure consisted of mating *Cre*-positive founders or their offspring with wild-type rats from a commercial source to obtain heterozygous (as well as wild-type) offspring. The advantage of using heterozygous offspring was two-fold. First, it is easier to create a large, stable colony of heterozygous animals without risking in-breeding; second, heterozygous rats are less likely than homozygous rats to exhibit unwanted side-effects of expressing the transgene since they express one wild-type chromosome. The expression profile of YFP was quantified in relationship to *ChAT* or *TH* expression for the F2 generation (or later) in these lines to allow for stabilization of the transgenes, and specificity was found to be greater than 90% for the offspring of one *Th::Cre* (Founder 3) and one *Chat::Cre* founder (Founder 5). No differences in *ChR2*-YFP expression profile were observed between F2s originating from the same founder.

(I) Cumulative responding at the active port for *Th::Cre*+ rats for the within-session contingency degradation test during maintenance, contingency degradation, and reacquisition.

(J) Quantification of total active nosepoke responses and stimulation trains delivered during maintenance, contingency degradation, and reacquisition. Response rate decreased during contingency degradation (two-tailed Wilcoxon signed-rank test, $p < 0.01$ for average nosepokes during maintenance versus contingency degradation).

(K) Quantification of responses at the active and inactive nosepoke ports for the last 5 min of maintenance, contingency degradation, and reacquisition. *Th::Cre*+ rats responded preferentially at the active nosepoke port at the end of all three phases (two-tailed Wilcoxon signed-rank test; $p < 0.01$ for maintenance and reacquisition; $p < 0.05$ for contingency degradation). In all panels, error bars indicate SEM.

Acute Slice In Vitro Electrophysiology

Coronal slices (325 μm) were obtained from adult rats (3 months or older) previously injected with virus (see [Supplemental Experimental Procedures](#) for details). In the analysis of in vitro electrophysiology, listed membrane potential refers to the initial potential measured immediately after attaining whole-cell configuration. To measure the magnitude of the hyperpolarization-activated inward I_h current, cells were held at -40mV , and a 500 ms voltage step to -120mV was applied. I_h was measured as the difference between the initial capacitive response to the voltage step (usually $\sim 20\text{--}40$ ms after the beginning of the voltage step) and the final steady-state current the end of the 500 ms pulse; responses greater than 115 pA were classified as $I_{h/\text{large}}$. The apparent input resistance was calculated from the linear portion of the steady-state I-V curve obtained by applying 500 ms hyperpolarizing current pulse steps. Action potential threshold was measured as the voltage at which the first-order derivative of the membrane potential (dV/dt) exhibited a sharp transition (typically $> 10\text{mV/ms}$). The action potential threshold was also used to set the threshold in determining spike fidelity (% of successful action potential after various light stimulation frequencies). Peak and steady-state photocurrents were measured from a 1 s light pulse in voltage-clamp mode. Series resistances were carefully monitored and recordings were not used if the series resistance changed significantly (by $>20\%$) or reached 20 $\text{M}\Omega$. Statistical analysis was performed with a two-tailed Student's *t* test, with a level of significance set at $p < 0.05$.

In Vivo Optrode Recording

Simultaneous optical stimulation and extracellular electrical recording were performed in anesthetized rats as described previously ([Gradinaru et al., 2007](#)). See [Supplemental Experimental Procedures](#) for details.

Fast-Scan Cyclic Voltammetry

Coronal brain slices (300–400 μm) were prepared from adult rats previously injected with virus. A carbon-fiber glass electrode was positioned in the NAc under fluorescent guidance. Voltammetric measurements were made every 100 ms by application of a triangular waveform (-0.4V to $+1.3\text{V}$, at 400V/s) to the carbon-fiber electrode versus an Ag/AgCl reference electrode. To estimate changes in DA release, background current at the electrode was subtracted from the current measured immediately following optical stimulation. Background-subtracted cyclic voltammogram showed peak oxidation and reduction currents at $\sim 650\text{mV}$ and -200mV , respectively, indicating that the signals were due to the detection of evoked DA release, and consistent with previous results. See [Supplemental Experimental Procedures](#) for additional details.

Behavioral Subjects

Fifteen male *Th::Cre* rats, 300–550 g at the start of the experiment, were individually housed in a light-regulated (12 hr light/dark cycle, lights on at 07:00) colony room. Food and water were available ad libitum throughout the experiment. Animal husbandry and all experimental procedures were in accordance with the guidelines from the National Institutes of Health and were approved in advance by the Gallo Center Institutional Animal Care and Use Committee.

Virus Injection and Implantation of Optical Fibers

Standard stereotaxic procedures were used to infuse virus (Cre-inducible ChR2 viral construct serotyped with AAV5 or AAV10 coat proteins; see [Supplemental Experimental Procedures](#) for details) in the VTA and implant optical fibers dorsal to the VTA. All coordinates are relative to bregma in mm. Although placements varied slightly from subject to subject, behavioral data from all subjects were included; see [Figure S3](#) for a summary of placements and associated behavioral variability. Two small burr holes were drilled unilaterally over the VTA at the following coordinates: AP -5.4 and -6.2 ; ML ± 0.7 . A custom-made 31 gauge infuser was used to deliver $1.0\text{ }\mu\text{l}$ of virus at two depths in each hole (DV -8.2 and -7.0 , all coordinates from skull surface) for a total of $4.0\text{ }\mu\text{l}$ virus delivered unilaterally to the VTA. Each $1.0\text{ }\mu\text{l}$ of virus was infused at a speed of $0.1\text{ }\mu\text{l}$ per minute using a syringe pump (Harvard Apparatus). The virus infuser was left in place for an additional 10 min following each injection before it was slowly removed. A third burr hole was drilled (AP -5.8 ; ML ± 0.7) for the insertion of an implantable optical fiber targeted just dorsal to the VTA

(DV -7.3). The implanted fiber was made in-house with optical fiber (BFL37-300, Thorlabs) and a metal ferrule (F10061F360, Fiber Instrument Sales) and was secured to the skull surface with five metal screws and dental cement. The following coordinates were used to infuse virus to other target structures: locus coeruleus (AP -9.6 , -10.5 ; ML 1.5 , DV -7.75), medial septum (AP 0.5 , ML 0.5 , DV -6.5 , -7.5), nucleus basalis (AP -1.5 , ML 2.5 , DV -7.0 , -6.0), and nucleus accumbens (AP 1.6 ; ML 2 ; DV 6 and 8).

Behavioral Apparatus

Experimental sessions were conducted in operant conditioning chambers (32 cm W $\times$ 32 cm L $\times$ 35 cm H; Med Associates Inc.) contained within sound-attenuating cubicles. The left panel was fitted with two nosepoke ports (5 cm from floor, separated by 18 cm), each with three LED lights at the rear. Prior to training sessions, rats were gently attached to patch cables made in-house with optical fiber (BFL37-200, Thorlabs) encased in a durable metal spring covering (PS95, Instech). These cables terminated with a metal ferrule connector (F10061F250, Fiber Instrument Sales) that was secured to the rats' cranial implant with a fitted ceramic sleeve (F18300SSC25, Fiber Instrument Sales) and were attached at the other end to an optical commutator (Doric Lenses). This commutator was connected via a second optical patch cable to a 100 mW DPSS 473 nm laser (OEM Laser Systems). The commutator was affixed to a counter-balanced lever arm (Med Associates) to minimize cable weight and provide lift when rats were rearing. Optical stimulation was controlled by a computer running Med PC IV (Med Associates) software, which also recorded responses at both nosepoke ports.

Behavioral Procedures

All behavioral tests were conducted > 5 weeks postsurgery. The tests are described in the order in which they were performed. For all test sessions, the start of a session was indicated to the rat by the illumination of a white house light and the onset of low-volume white noise (65 dB) to mask extraneous sounds. Peak light output during photostimulation was estimated to be $\sim 1.5\text{--}2\text{ mW}$ at the tip of the implanted fiber for each session, and $\sim 0.45\text{--}0.6\text{ mW/mm}^2$ at the targeted tissue 500 μm from the fiber tip. This peak light power was based on measuring the average light power for the pulsed light parameters used during experiments (20 Hz, 5 ms duration), and then correcting for the duty cycle to arrive at the peak power (in this case by dividing by 0.1). The power density estimate was based on the light transmission calculator at www.optogenetics.org/calc.

Fixed-Ratio 1 (FR1) Training

During the first training session, both active and inactive nosepoke ports were baited with a crushed cereal treat to facilitate initial investigation. Rats were given four daily sessions of two hours each in which they could respond freely at either nosepoke port. For all rats (*Th::Cre+* and *Th::Cre-*), a response at the active port resulted in the delivery of a 1 s train of light pulses (20 Hz, 20 pulses, 5 ms duration). Concurrently, the LED lights in the recess of the active port were illuminated, providing a visible cue whenever stimulation was delivered. Responses at the active port made during the 1 s period when the light train was being delivered were recorded but had no consequence. Responses at the inactive port were always without consequence.

Duration-Response Test

The duration-response test measured the rats' response to stimulation trains that varied systematically in length. As before, all stimulation trains consisted of pulses of 20 Hz frequency and 5 ms duration. The test was organized into nine trials, and in each trial nosepokes at the active port were rewarded with stimulation trains of a specific length (100, 80, 60, 40, 20, 10, 5, 3, or 1 pulse/train). The first trial consisted of the longest stimulation length (100 pulses); the next trial consisted of the next longest stimulation length (80 pulses), and so on in descending order. A series of all nine trials was considered to be a "sweep." A session consisted of four consecutive sweeps. The data presented is an average of all eight sweeps from two consecutive days of testing. The start of a trial was signaled by the illumination of the house light and the onset of low-level white noise as described above. Three "priming" trains of stimulation were then delivered noncontingently to inform the rat of the stimulation parameters that would be available on the upcoming trial. The separation between these trains was equal to the length of stimulation or 1 s, whichever longer. Once the priming trains had finished, the subject then

had the opportunity to earn up to 60 stimulation trains during that trial; this was true regardless of the length of stimulation delivered. The length of an individual trial was $60 \times$ the length of stimulation train or 60×1 s, whichever was longer. For stimulation lengths of 20 pulses or greater, a new stimulation train could be earned as soon as the previous train had finished. For stimulation lengths of ten pulses or fewer, there was a short timeout (1 s – length of stimulation train) before the next train could be earned. This was to ensure that it was physically possible for subjects to respond for all available trains regardless of the stimulation length used. At the end of each trial, the house light and the white noise were turned off. After an inter-trial interval of approximately 1 min, the next trial began.

Extinction and Reacquisition

During this 1.5 hr test session subjects were initially given 30 min of regular FR1 training. Subsequently, a within-session extinction period began. During this phase, responses at the active port were recorded but had no consequence. After 30 min of extinction had elapsed, 5 stimulation trains (each train 1 s long, intertrain interval = 1 s) were delivered to signal the renewed availability of reinforcement at the active port. For the rest of the session rats were reinforced on an FR1 basis for responses at the active port.

Contingency Degradation

On the day before the contingency degradation test, subjects were given an additional 1 hr FR1 training session. The number of stimulation trains delivered during this session (dependent on subjects' responses at the active port) was used to calculate the average rate of stimulation for the contingency degradation portion of the experiment. The next day, rats were given 30 min of regular FR1 training. Subsequently, a within-session contingency degradation period began. During this phase, stimulation trains were delivered pseudorandomly and noncontingently at a rate that was matched to each subjects' performance during FR1 training on the previous day. After a further 30 min had elapsed, a reacquisition phase was initiated. During this phase, stimulation was once again contingent on a response made at the active port. The total length of this test was 1.5 hr. During this experiment, whenever a stimulation train was delivered (regardless of whether it had been earned by a nosepoke response or was delivered non-contingently) the LED lights in the active port were concurrently illuminated.

Data Analysis

The behavioral data was analyzed with nonparametric tests as specified (e.g., Wilcoxon signed-rank test for paired data, Mann Whitney test for unpaired data) coupled with Bonferroni tests to control for multiple comparisons where appropriate. This statistical approach resulted in a conservative measure of statistical significance. Given that the behavioral data was distributed in a non-Gaussian manner, and the different behavioral conditions varied greatly in their variance (e.g., Figure 6B), a parametric ANOVA would not have been an appropriate statistical choice for this data set. For the duration-response test (Figure 6E), before averaging across rats, an individual rat's response rate was divided by the response rate for the condition with the maximum responding. Since the condition that corresponded to the maximum rate was not the same for all rats, on average this resulted in a maximum normalized response rate below 1.

SUPPLEMENTAL INFORMATION

Supplemental Information includes three figures, one table, and Supplemental Experimental Procedures and can be found with this article online at doi:10.1016/j.neuron.2011.10.028.
