Convolutional  
neural networks

Devis TUIA

Image  
processing  
for Earth  
Observation

EPFL, fall semester  
2024

# Content (6 weeks)

- W1 General concepts of image classification / segmentation
  - Traditional supervised classification methods (RF)
- W2 Traditional supervised classification methods (SVM)
  - Best practices
- W3 Elements of neural networks
- W4 **Convolutional neural networks**
- W5 Convolutional neural networks for semantic segmentation
- W6 Sequence modeling, change detection

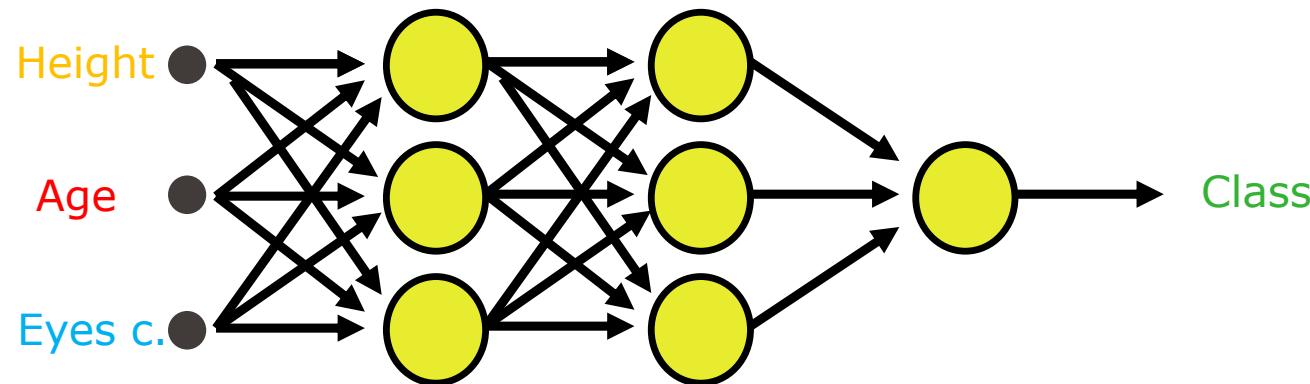

# Convolutional neural networks

Larger inputs need weight sharing

From dense to convolutional layers

Padding, stride and pooling

# MLPs consider feature interactions only

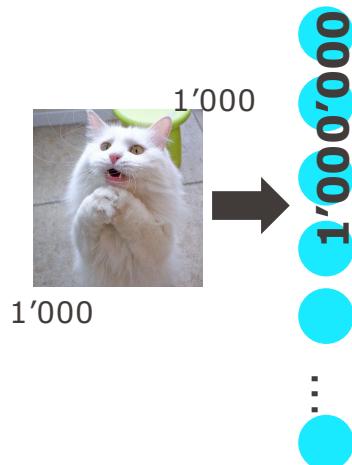

- MLPs consider each datapoint as a point in feature space
- It is often the best we can do if we have *tabular* data

ID	Height	Age	Eye color	class
1	65	7	blue	dog
2	34	3	brown	cat
3	55	12	brown	cat

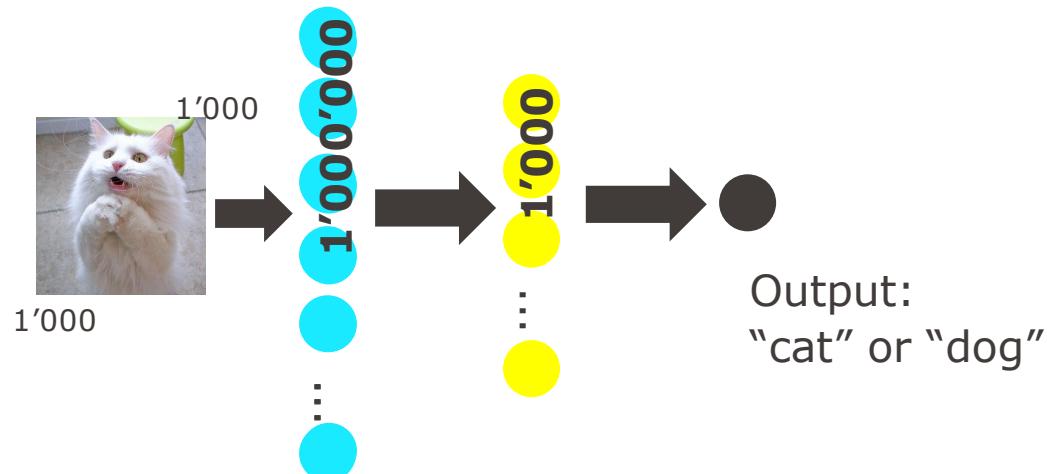

# When dealing with images...

- One could consider every pixel as a feature
- Ex: 1MPixel =  $1000 \times 1000$  pixels = 1 million pixels\*
- We could represent them as a table with a million features (1 per pixel\*)

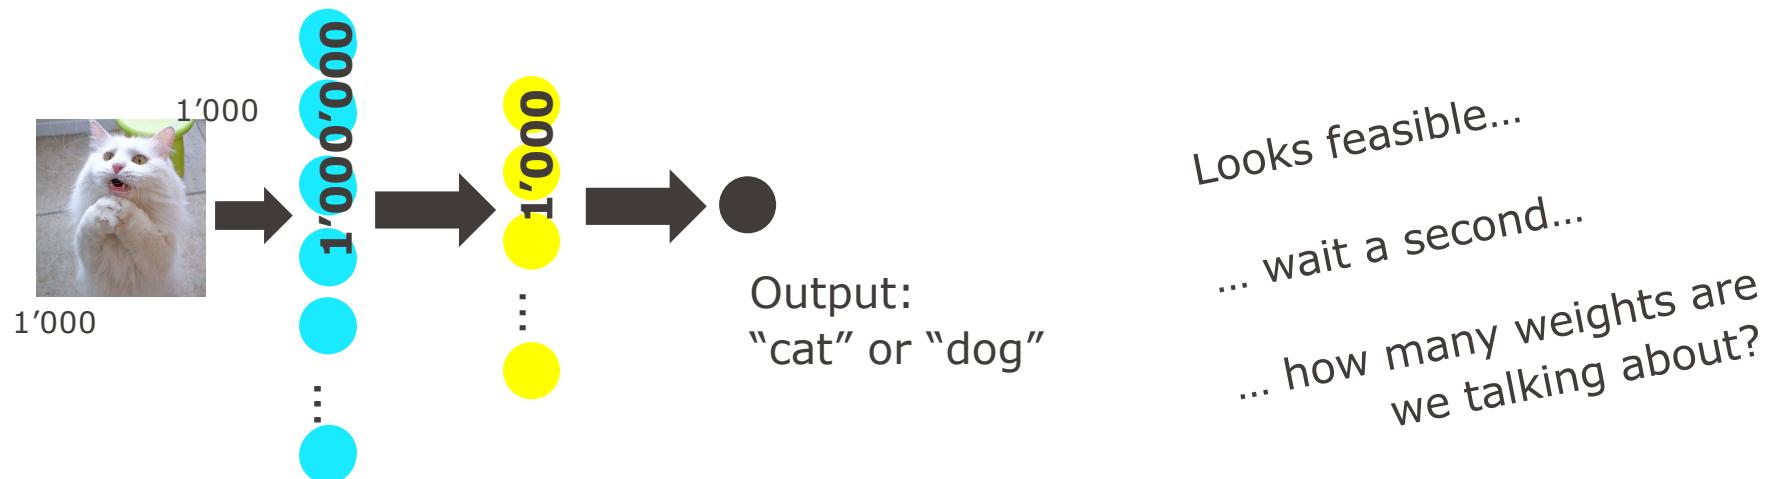

# When dealing with images...

- One could consider every pixel as a feature
- Ex: 1MPixel =  $1000 \times 1000$  pixels = 1 million pixels\*
- We could represent them as a table with a million features (1 per pixel\*)

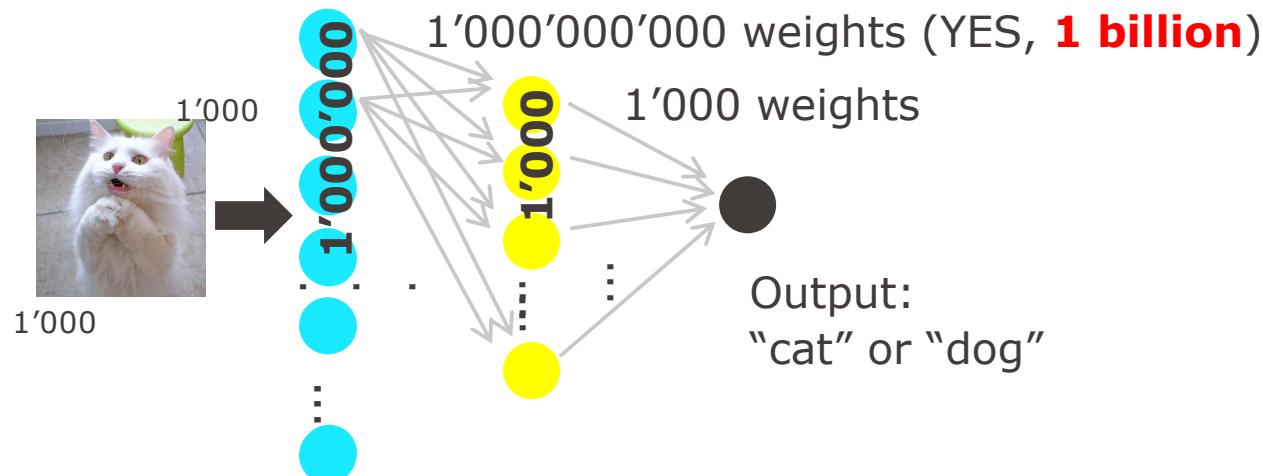

# When dealing with images...

- One could consider every pixel as a feature
- Ex: 1MPixel =  $1000 \times 1000$  pixels = 1 million pixels\*
- We could represent them as a table with a million features (1 per pixel\*)

# When dealing with images...

- One could consider every pixel as a feature
- Ex: 1MPixel =  $1000 \times 1000$  pixels = 1 million pixels\*
- We could represent them as a table with a million features (1 per pixel\*)

# ... it becomes a bigger problem.

- So we are talking 1 billion learnable weights.
- The value of a hidden neuron can be expressed as

$$h[i, j] = u[i, j] + \sum W[i, j, k, l] \cdot x[k, l]$$

- Where  $i, j$  and  $k, l$  are pixels locations in the image

# ... it becomes a bigger problem.

- So we are talking 1 billion learnable weights.
- The value of a hidden neuron can be expressed as

$$h[i, j] = u[i, j] + \sum_{k, l} W[i, j, k, l] \cdot x[k, l]$$

Meaning: each feature in the hidden layer  $h$  depends on **ALL** locations of the input image (hint: look at the sum on  $k, l$ ).

- Where  $i, j$  and  $k, l$  are pixels locations in the image
  - we want to express a pixel  $(i, j)$  as a combination of all other pixels  $(k, l)$
  - each neuron  $h$  is specific to one pixel location  $i, j$

# ... it becomes a bigger problem.

- So we are talking 1 billion learnable weights.
- The value of a hidden neuron can be expressed as

$$\begin{aligned} h[i, j] &= u[i, j] + \sum_{k, l} W[i, j, k, l] \cdot x[k, l] \\ &= u[i, j] + \sum_{a, b} V[i, j, a, b] \cdot x[i + a, j + b] \end{aligned}$$

- Where  $i, j$  and  $a, b$  are pixels locations in the image
  - $k = i + a$  (we just re-express by relative positions)
  - $j = j + b$

# ... it becomes a bigger problem.

- So we are talking 1 billion learnable weights.
- The value of a hidden neuron can be expressed as

$$h[i, j] = u[i, j] + \sum_{k, l} W[i, j, k, l] \cdot x[k, l]$$

Final value of the feature (specific to a location  $i, j$ )

$$= u[i, j] + \sum_{a, b} V[i, j, a, b] \cdot x[i + a, j + b]$$

Bias (specific to a location  $i, j$ )

Filter weights (arrows in slide 8) specific to pairs of locations

Original pixel values at a location  $(i+a, j+b)$

# ... it becomes a bigger problem.

- So we are talking 1 billion-ish learnable weights.
- To learn this, you would need m(b)illions of examples and a lot of computational power
- The population of cats and dogs on the planet is around 1.5 billions...
- We need to be more clever than that.
  
- What can we do?

# Evidence #1

## Location is NOT so important

- Our visual system recognizes objects independently of their specific location in the image.
- You will re-use the same filters at different locations

Source: petguide, boredpanda, countryliving

# Evidence #1

## Location is NOT so important

- This can simply be implemented in the neuron equation by removing dependence of the weights on location:

$$h[i, j] = u[i, j] + \sum_{a, b} V[i, j, a, b] \cdot x[i + a, j + b]$$

$$h[i, j] = u + \sum_{a, b} V[a, b] \cdot x[i + a, j + b]$$

- This implements **translation invariance** and is the main reason why CNNs are nowadays trainable.

# Evidence #1

## Location is NOT so important

- In other words (example involving a  $4 \times 5$  pixels image):

# Evidence #2

## Global context is NOT so important

- Our visual system recognizes objects (mostly) by looking at local features.
- You don't need to encode neuron dependencies between far away parts of the image

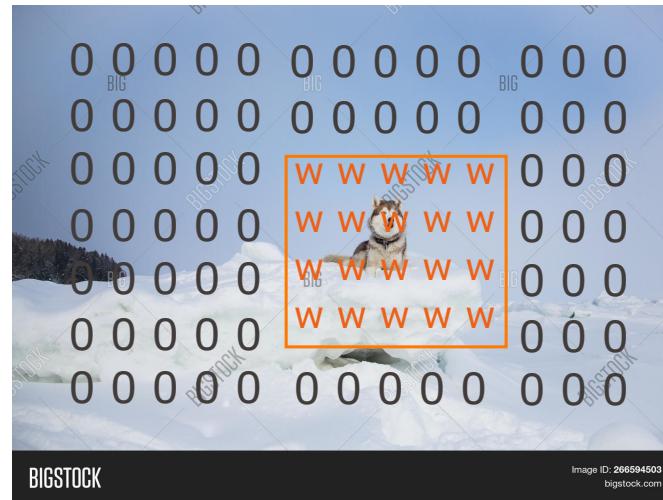

Source: bigstock, petguide, boredpanda, countryliving

# Evidence #2

## Global context is NOT so important

- In other words, the relevant information must be close to location  $i, j$
- The weights should be nonzero only in the vicinity of the pixel you are considering

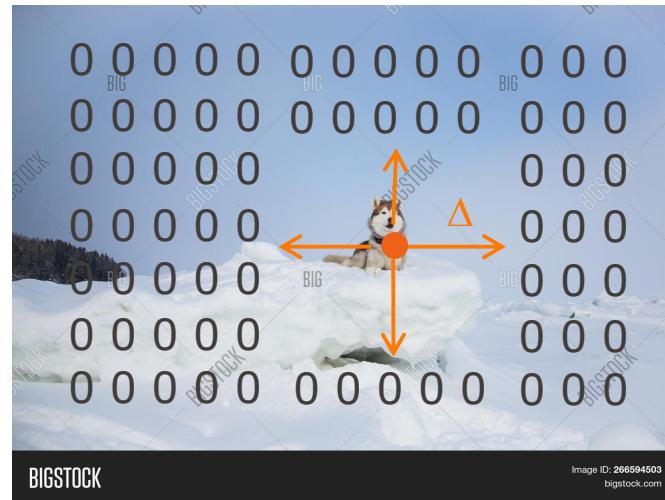

Source: bigstock, petguide, boredpanda, countryliving

# Evidence #2

## Global context is NOT so important

- In other words, the relevant information must be close to location  $i, j$
- The weights should be nonzero only in the vicinity of the pixel you are considering

# This is called a (2D) convolution

- The weights are organized as a filter, slid over the image
- In the original example of cats and dogs:
  - Location-specific :  $(i \times j \times a \times b)$  weights:  $10^9$
  - Translation invariant :  $(a \times b)$  weights:  $10^6$
  - Local windows :  $((2\Delta+1)^2)$  weights:  $9 * 1000$

# Exercise

- Calculate the result of the following convolutional filters ( $W$ ) when applied to an image ( $I$ ):

$I$

3	1	4	3
3	2	3	1
4	3	6	4
3	3	1	7

$W_1$

1	-1	2
3	1	4
5	-2	9

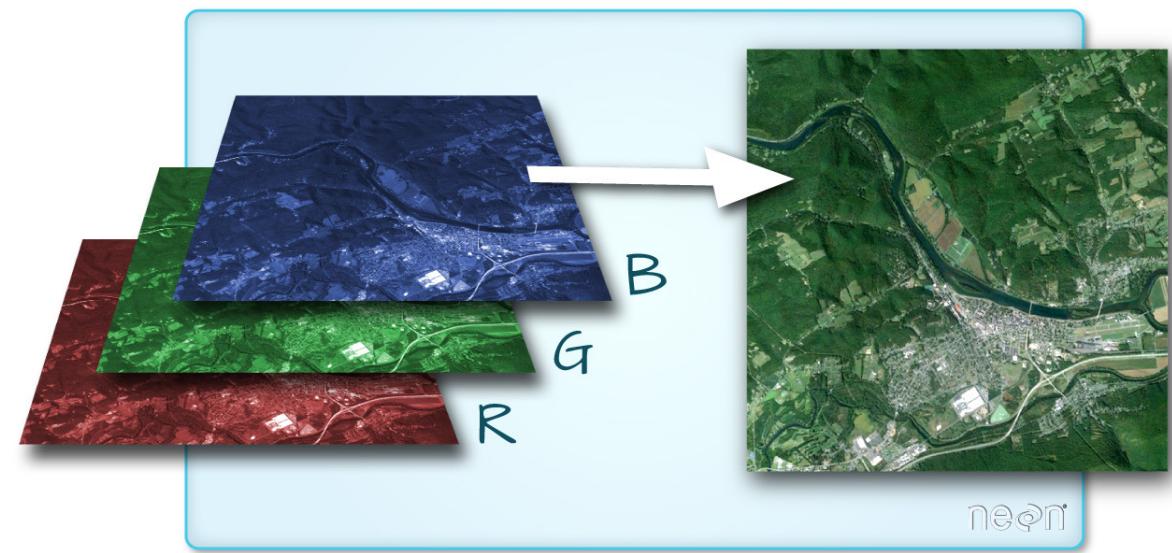

$W_2$

1	1	1
1	1	1
1	1	1

- What is the dimension of the output? Any idea why?

# Images are 3D tensors though

- Images have (at least) 3 bands: Red, Green, Blue

# Images are 3D tensors though

- Images have (at least) 3 bands: Red, Green, Blue
- The result of a 2D convolution is the sum of 2D filters over the single input bands:

$$h[i, j] = u + \sum_{a=-\Delta}^{\Delta} \sum_{b=-\Delta}^{\Delta} V[a, b] \cdot x[i + a, j + b]$$

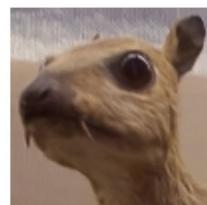

$$h[i, j] = u + \sum_{a=-\Delta}^{\Delta} \sum_{b=-\Delta}^{\Delta} \sum_c V[a, b] \cdot x[i + a, j + b, c]$$

# But it's just sliding windows...

- Yes, but
- Different filters have different effects
- This time, the filters are learned
  - We don't know them in advance
  - We learn the weights by gradient descent

## Examples

(wikipedia)

[courses.d2l.ai/berkeley-stat-157](https://courses.d2l.ai/berkeley-stat-157)

$$\begin{bmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{bmatrix}$$

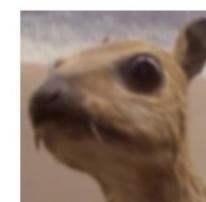

Edge Detection

$$\begin{bmatrix} 0 & -1 & 0 \\ -1 & 5 & -1 \\ 0 & -1 & 0 \end{bmatrix}$$

Sharpen

$$\frac{1}{16} \begin{bmatrix} 1 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 1 \end{bmatrix}$$

Gaussian Blur

# Learning more filters

Attention!  $k$  here is a filter index, not the position index as in previous slides...

- Convolutional filters have different effects
- So we want to learn more than 1 filter
- For  $k$  filters:

$$h[i, j] = u + \sum_{a=-\Delta}^{\Delta} \sum_{b=-\Delta}^{\Delta} \sum_c V[a, b] \cdot x[i + a, j + b, c]$$

$$h[i, j, k] = u + \sum_{a=-\Delta}^{\Delta} \sum_{b=-\Delta}^{\Delta} \sum_c V[a, b, k] \cdot x[i + a, j + b, c]$$

# Convolutional neural networks

Larger inputs need weight sharing

From dense to convolutional layers

Padding, stride and pooling

# Convnets are a bit like lego playing

- Now you know how to compute a convolutional filter
- A convolutional network is a stack of such convolutions

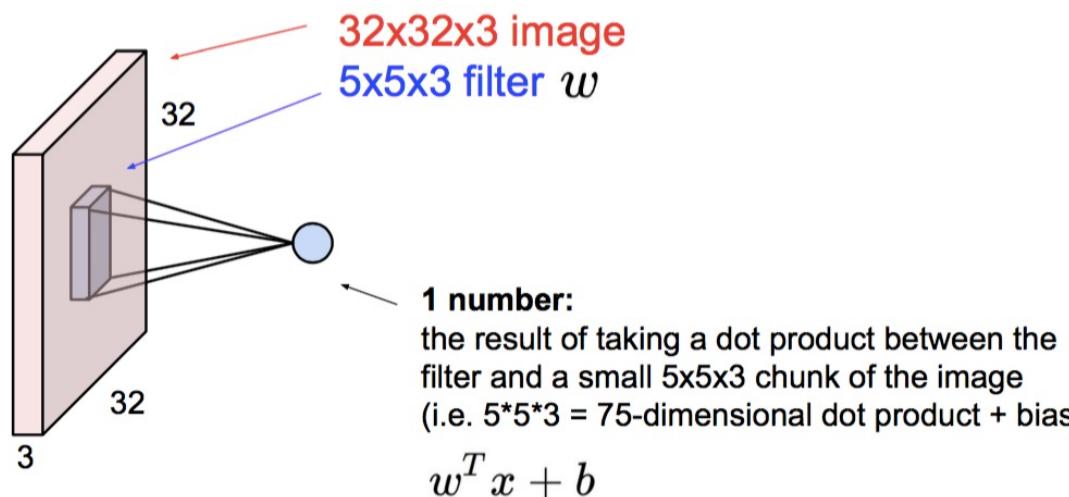

<http://www.inference.vc/deep-learning-is-easy/>

# Convolutional neural networks

In convolutional neural networks, the filters are spatial (on 2D grids).

- local : they convolve the values of the image in a local window

[From Wegner, ETH]

# Convolutional neural networks

In convolutional neural networks, the filters are spatial (on 2D grids).

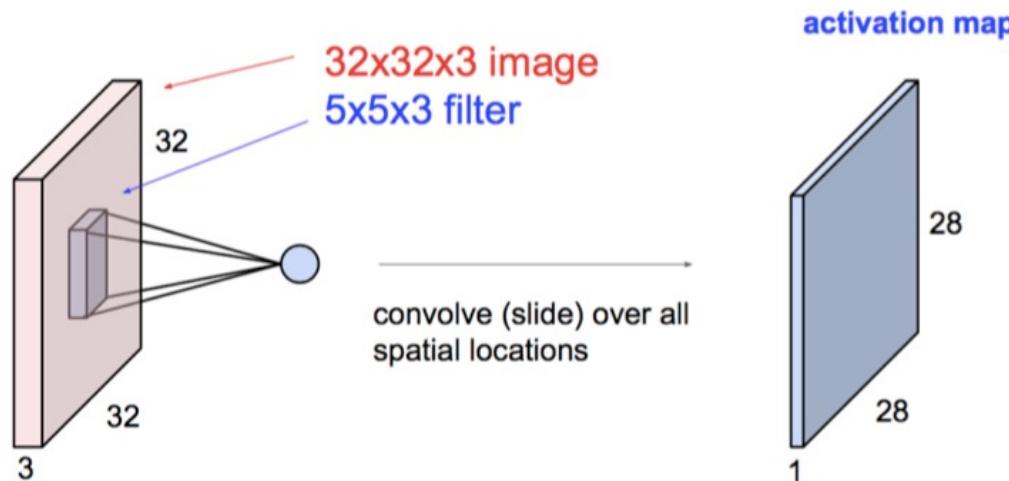

- local : they convolve the values of the image in a local window
- the convolution is followed by a nonlinearity to make the result nonlinear.
- your nonlinearity can be a sigmoid or (easier to compute) a Rectified Linear Unit (ReLU):

$$f(x) = \max(f(x), 0)$$

# Convolutional neural networks

In convolutional neural networks, the filters are spatial (on 2D grids).

- local : they convolve the values of the image in a local window
- shared: the same filter is applied everywhere in the image, leading to an **activation map**

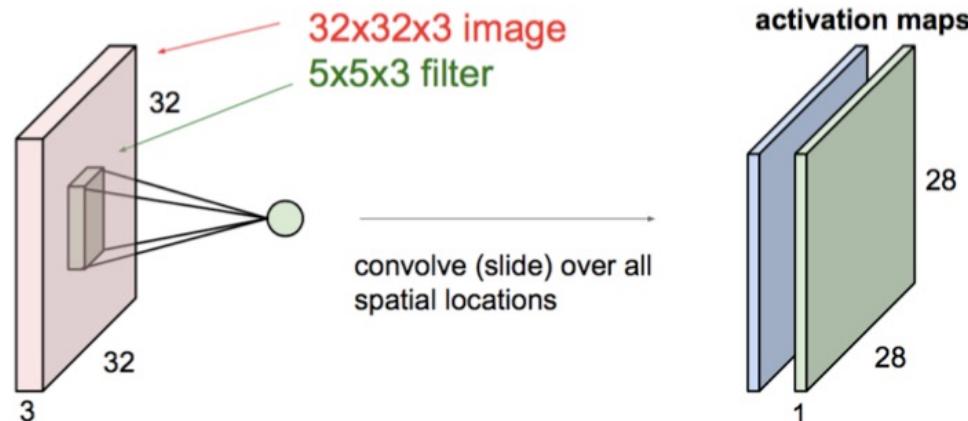

[From Wegner, ETH]

# Convolutional neural networks

In convolutional neural networks, the filters are spatial (on 2D grids).

- local : they convolve the values of the image in a local window
- shared: the same filter is applied everywhere in the image, leading to an activation map
- **many filters are learned in parallel**

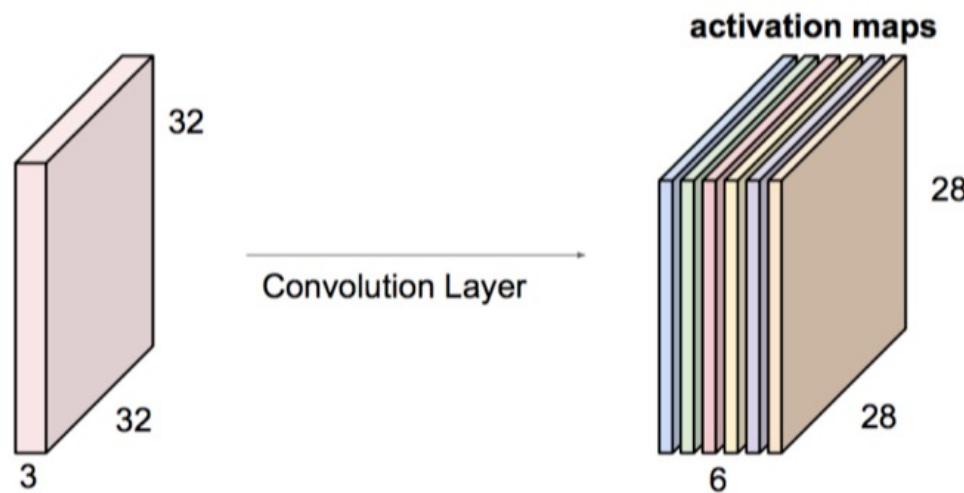

[From Wegner, ETH]

# Convolutional neural networks

In convolutional neural networks, the filters are spatial (on 2D grids).

- local : they convolve the values of the image in a local window
- shared: the same filter is applied everywhere in the image, leading to an activation map
- **many filters are learned in parallel (in this case 6)**

[From Wegner, ETH]

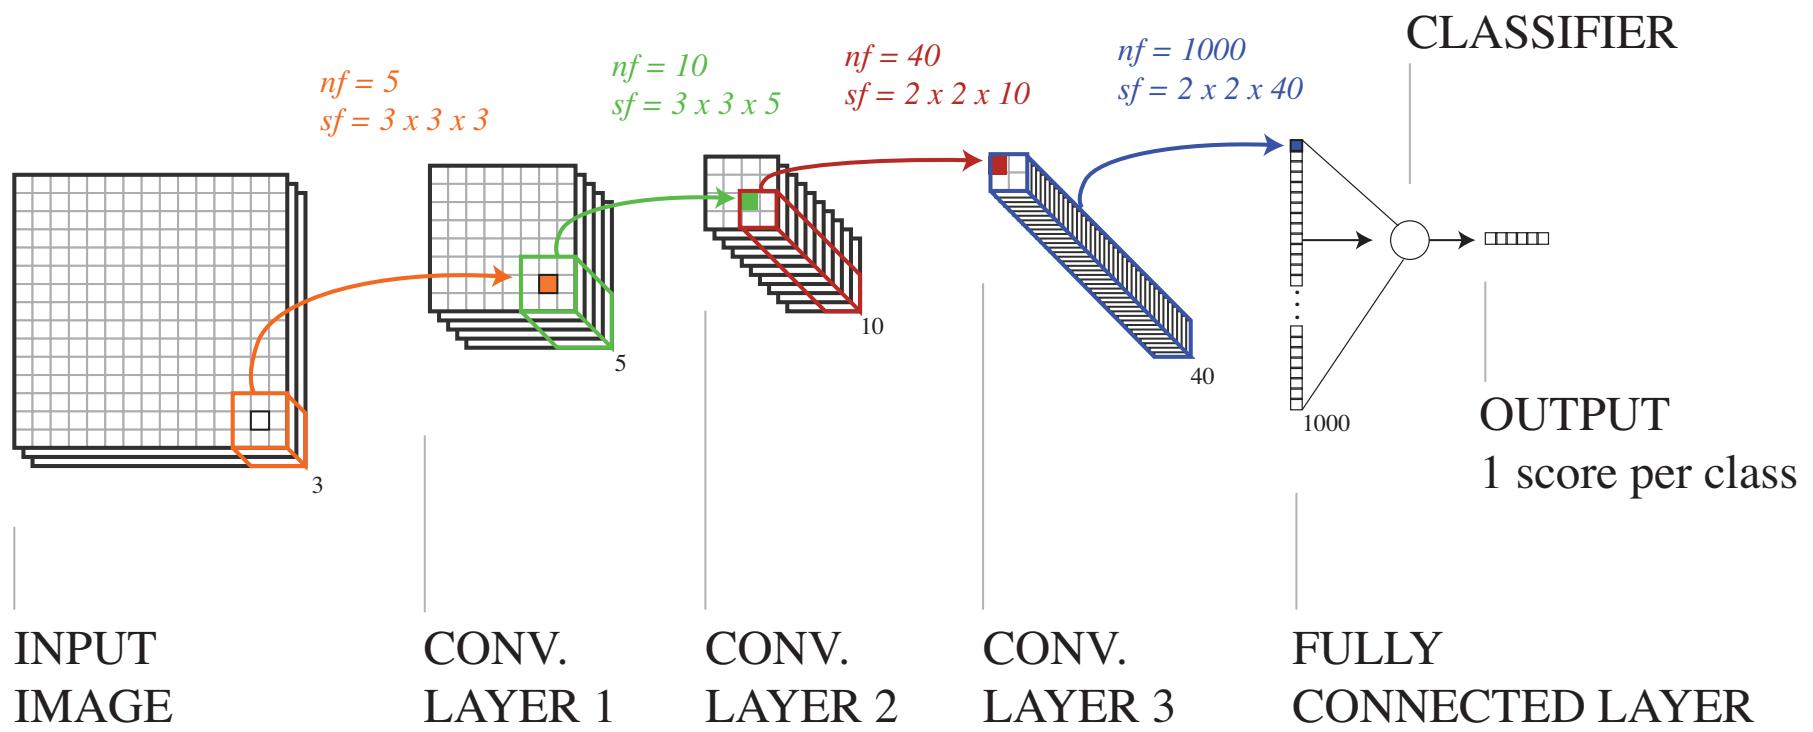

# Convnets are a bit like lego playing

- The thing is: you need to be sure of the sizes of your activation maps
- Like Legos, they need to fit to eachother

<http://www.inference.vc/deep-learning-is-easy/>

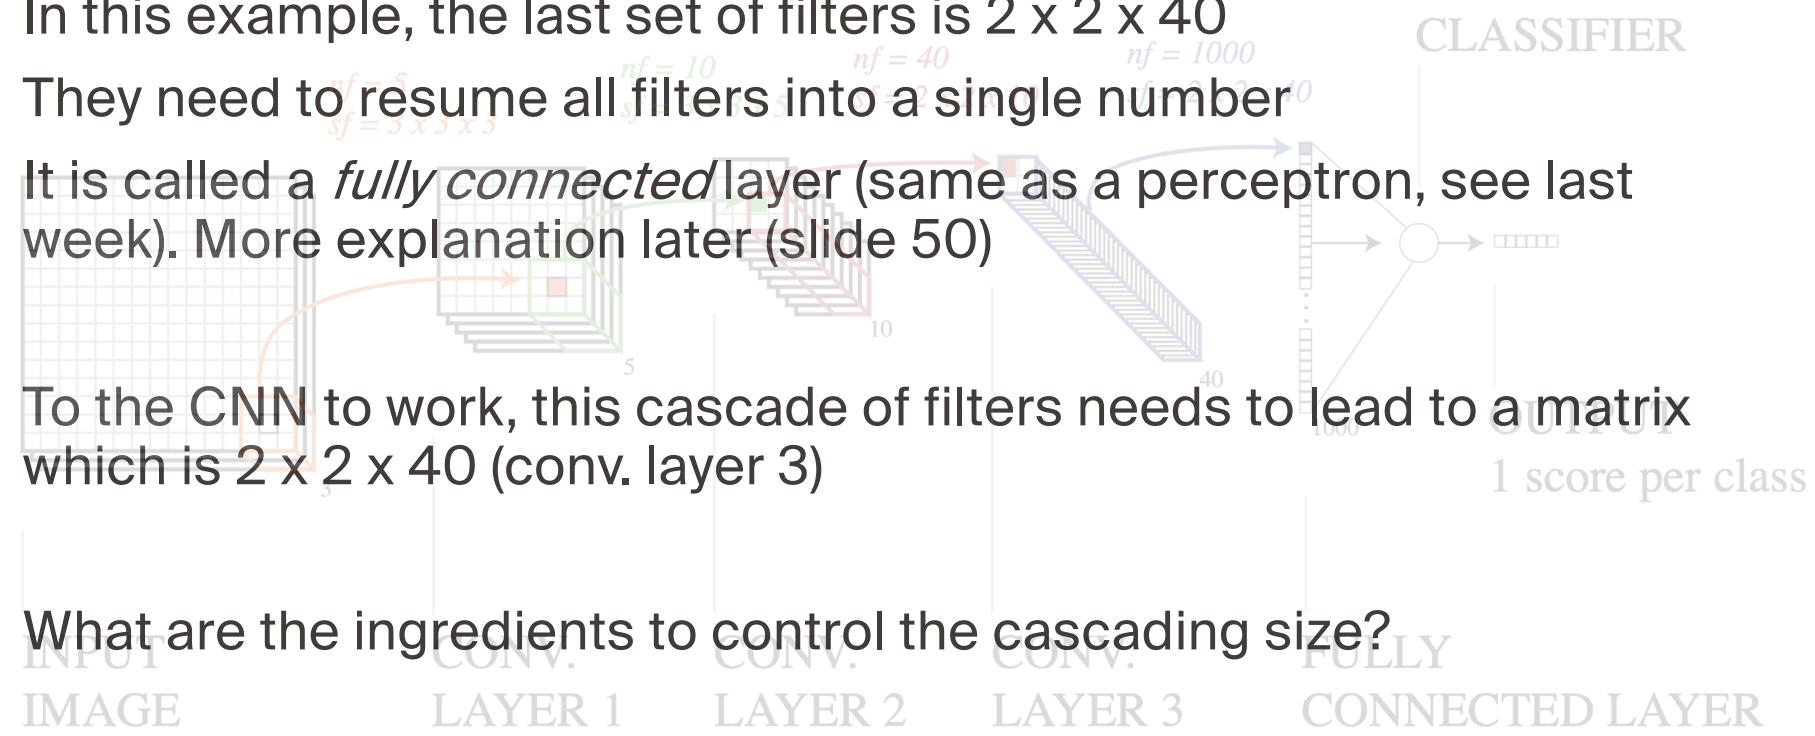

# Convnets are a bit like lego playing

# Convnets are a bit like lego playing

- In this example, the last set of filters is  $2 \times 2 \times 40$
- They need to ~~resume~~ all filters into a single number
- It is called a *fully connected* layer (same as a perceptron, see last week). More explanation later (slide 50)

# Ingredient #1 padding

$$I$$

3	1	4	3
3	2	3	1
4	3	6	4
3	3	1	7

$$W_1$$

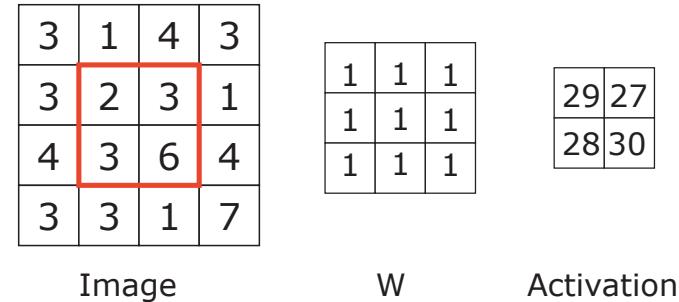

1	-1	2
3	1	4
5	-2	9

- In the previous exercise (slide 23), the resulting activation map was of size  $2 \times 2$
- The convolution by  $W_1$  could only consider the four pixels centered in the red square
- With an input image of size  $(n_h \times n_w)$  and a filter  $(k_h \times k_w)$ , the output size is:

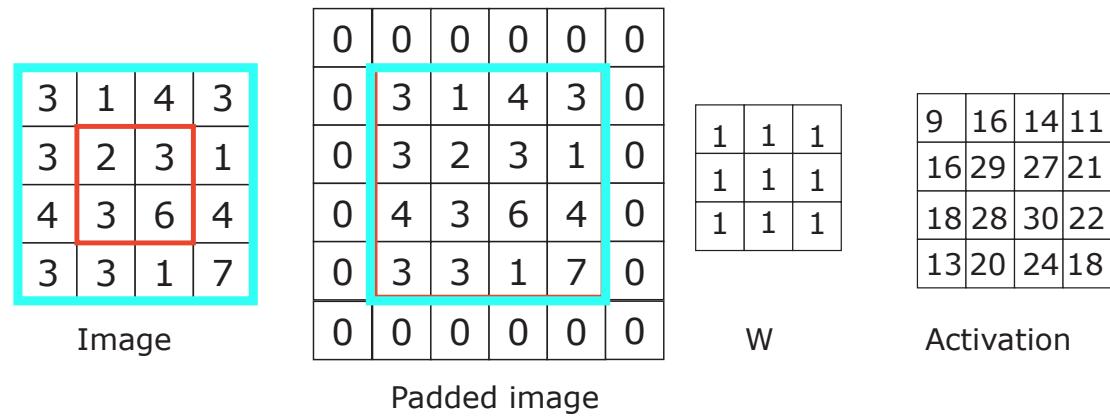

$$(n_h - k_h + 1) \times (n_w - k_w + 1)$$

# Ingredient #1 padding

- Without padding

- With padding

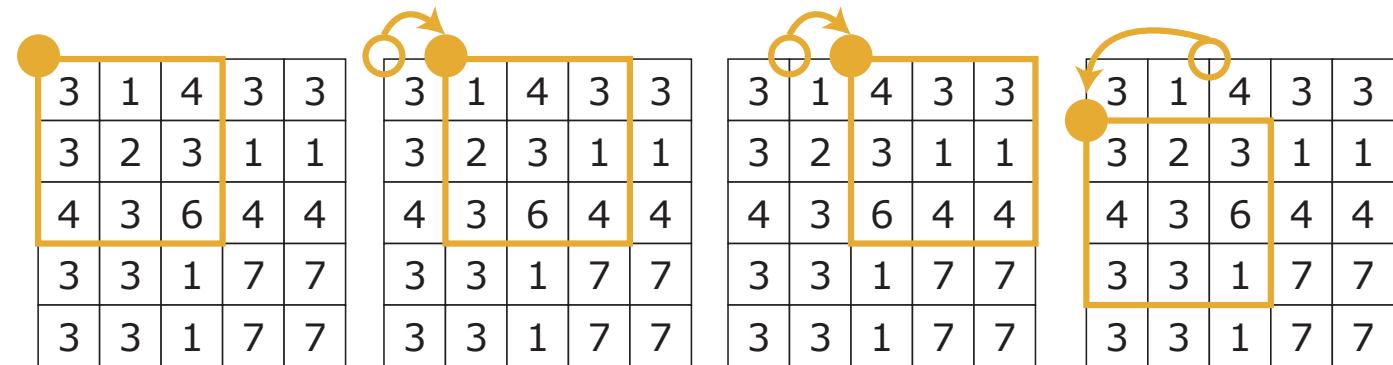

# Ingredient #2 stride

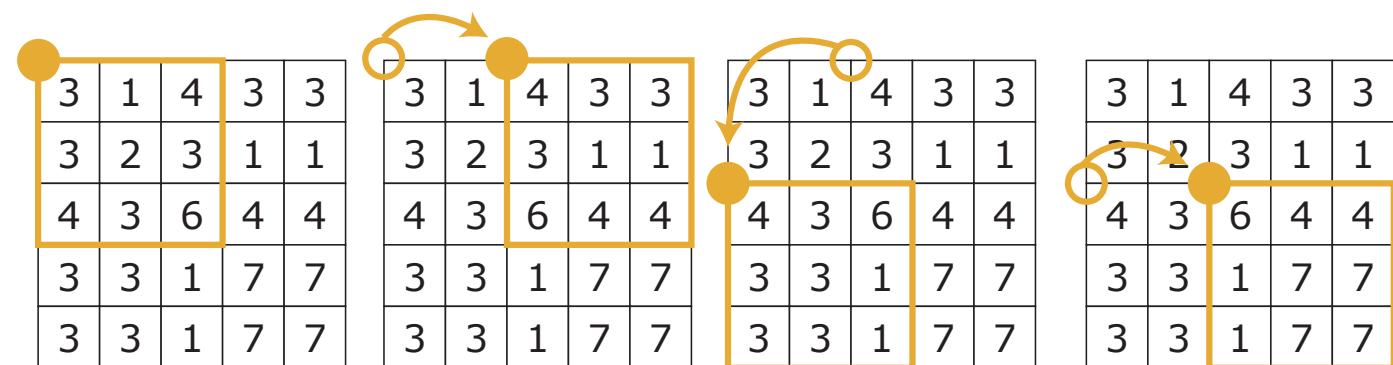

- By default, convolutions scan the image from top left to bottom right, one pixel at a time
- We call this *stride of 1*
- Sometimes, to reduce resolution or need less filters, we can compute only one every  $k$  pixels, which leads to *stride  $k$*
- *If you use stride = 2*, the activation map size is half of the original image
- Different strides in row and column are rarely used.

# Ingredient #2 stride

Filter 3 x 3, Padding = 0, Stride 1. Activation map size: 3 x 3

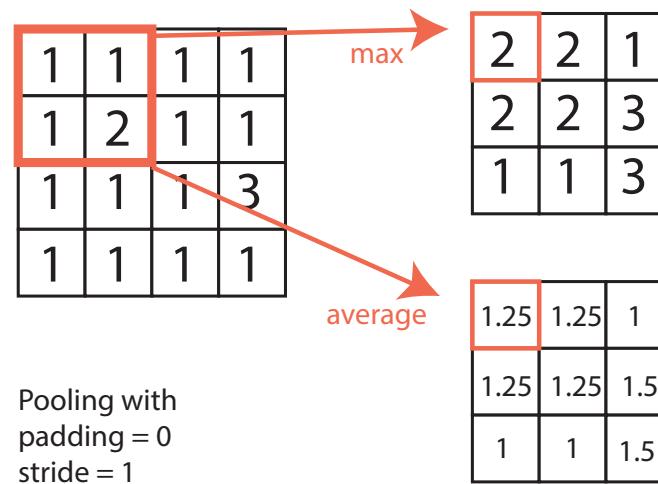

Filter 3 x 3, Padding = 0, Stride 2. Activation map size: 2 x 2

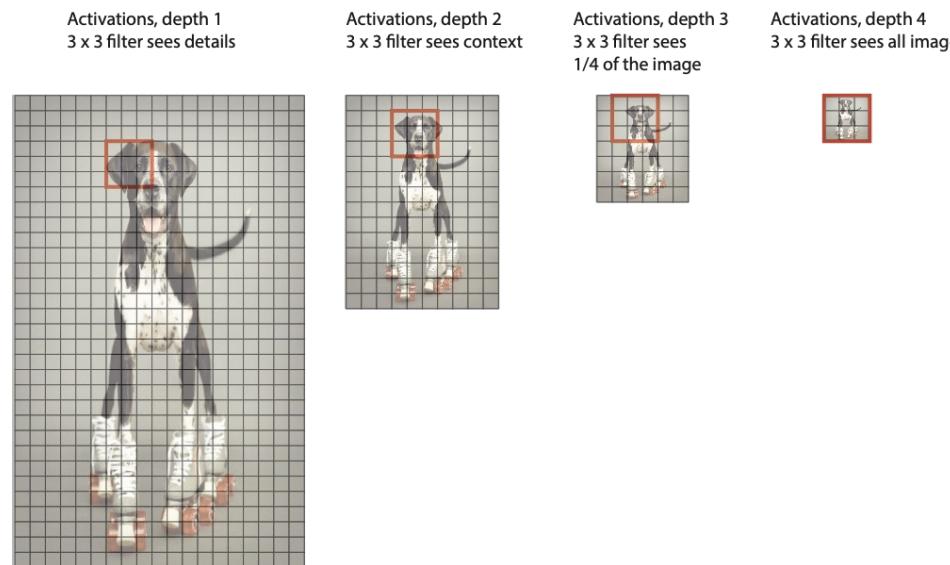

# Ingredient #3 pooling

- Pooling is an operation that decreases the size of the activation map
- It seems similar to stride (it reduces size), but *selects the information to carry over*, rather than skipping calculations
- Pooling works by applying a function locally in an activation map:

# Ingredient #3 pooling

- Pooling has desirable effects:
  - It increases the receptive field, i.e. allows to see more of the image with a fixed size filter
    - Example: if we constantly apply  $3 \times 3$  filters, this is what they “see”

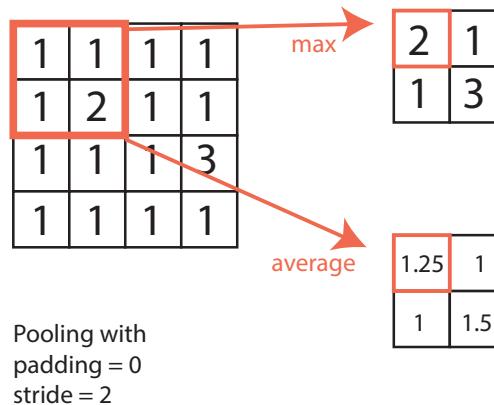

# Ingredient #3 pooling

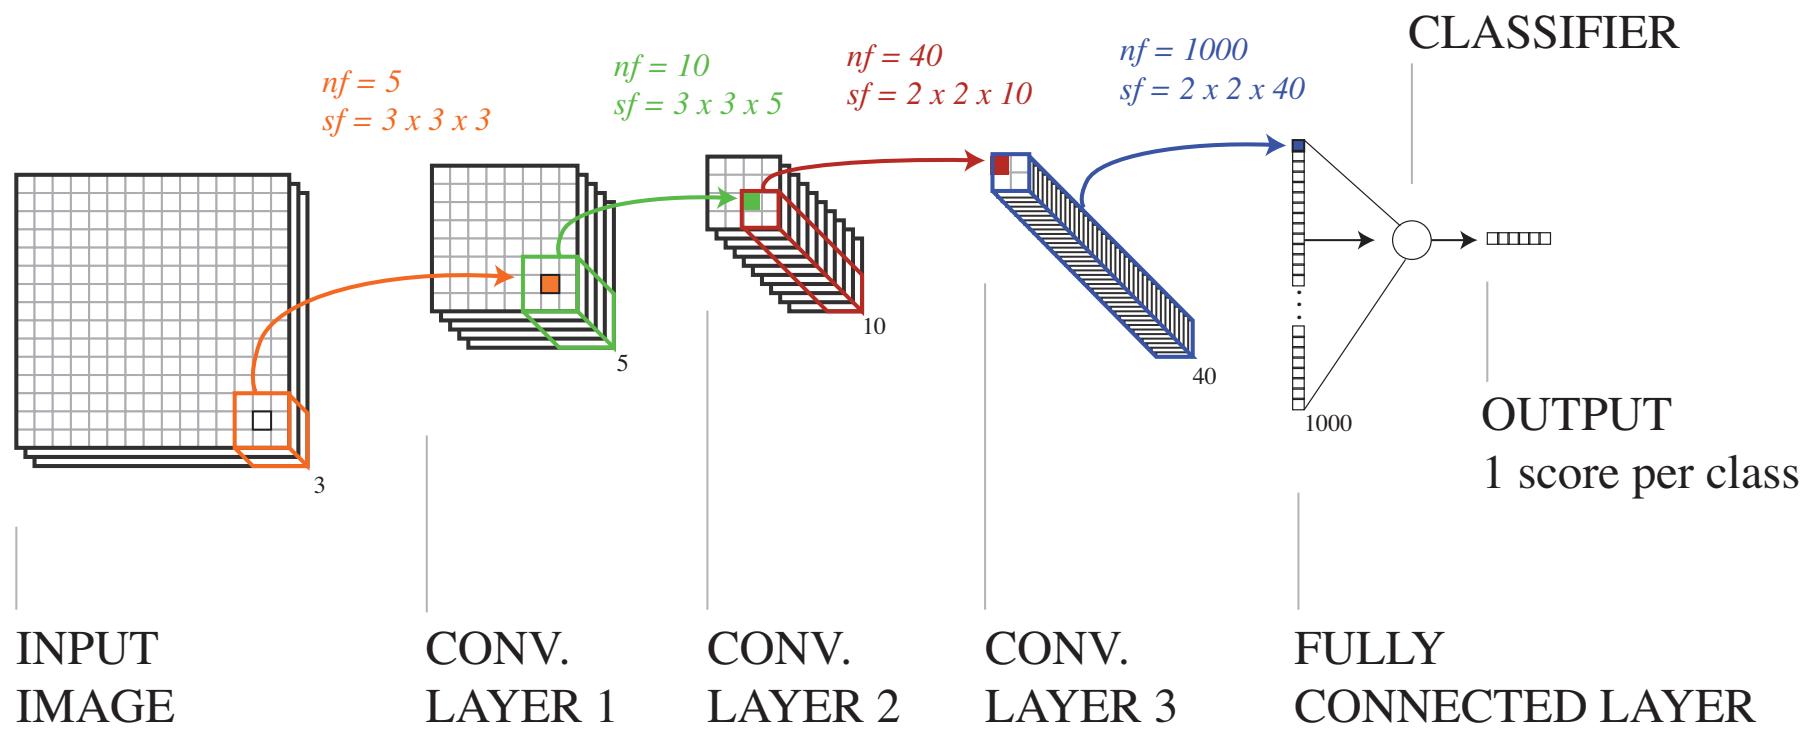

- Pooling has desirable effects:
  - It increases the receptive field, i.e. allows to see more of the image with a fixed size filter
  - Max pooling helps with translation invariance (the exact pixel position of the max is not so important, by shifting the image by 1 pixel the result is the same)

# Ingredient #3 Pooling

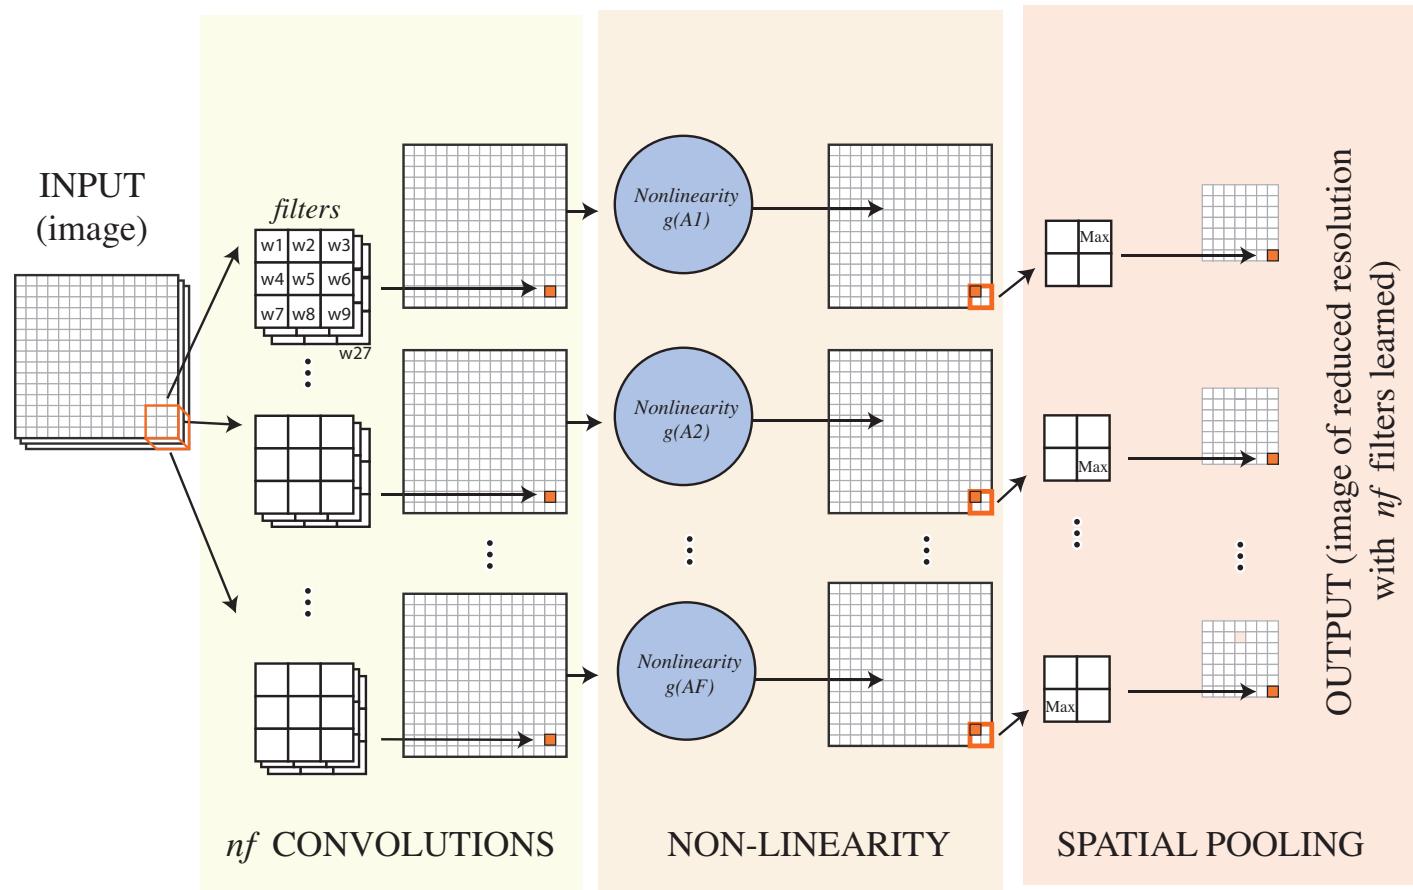

- Pooling has desirable effects:
  - It increases the receptive field, i.e. allows to see more of the image with a fixed size filter
  - Max helps with translation invariance (the exact pixel position of the max is not so important, by shifting the image by 1 pixel the result is the same)
- Stride is often set equal to the pooling size

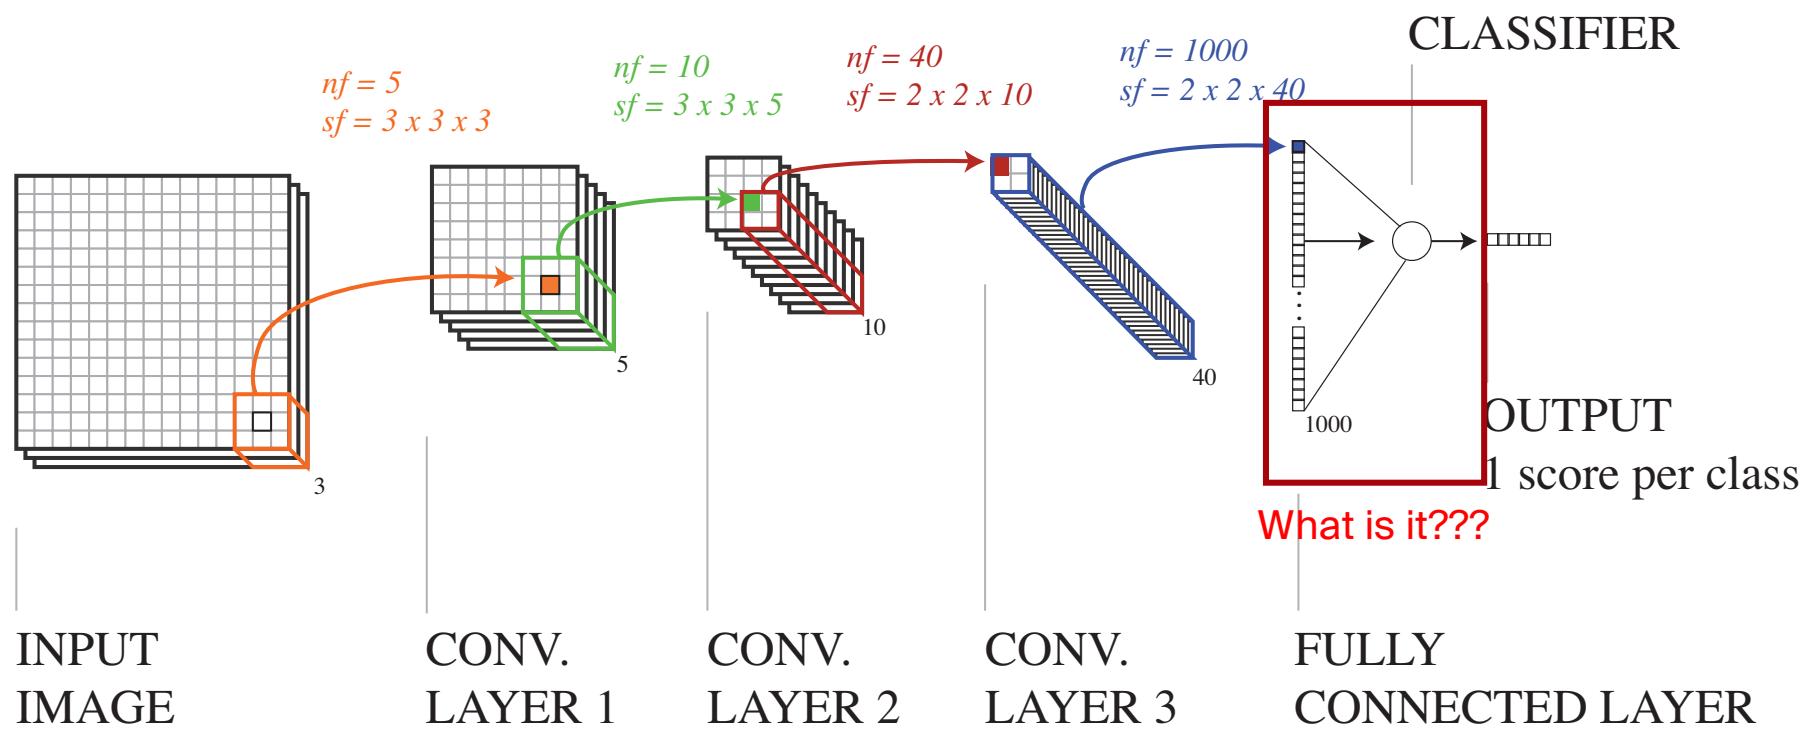

# From the simplified convnet view...

# ... to the real one (for 1 layer, then repeat)

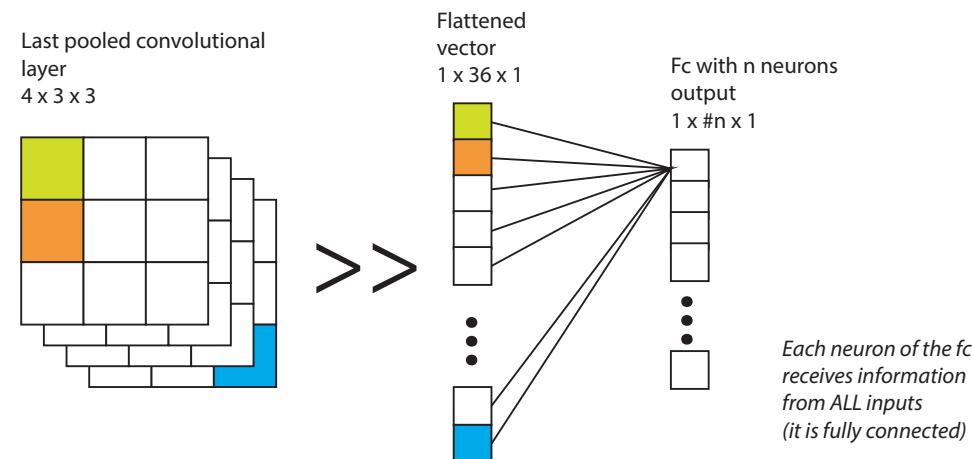

# From the simplified convnet view...

# The fully connected layer

- More or less what we saw in the MLP last week.
- First we flatten the tensor we have (either by learning a layer combining all activations (as in previous slide) or by simple reordering (as below))
- Then we use a fully connected layer (all inputs are mixed in each neuron of the output) and learn many neurons (here  $n$ )
- This final Fc layer is used for classification

# Convolutional neural networks

Larger inputs need weight sharing

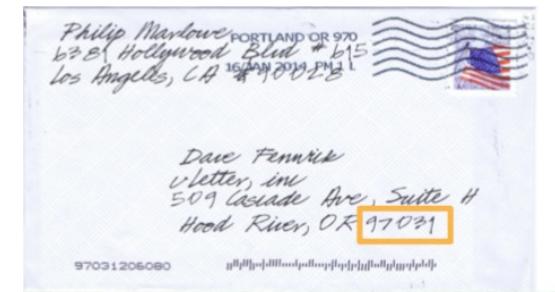

From dense to convolutional layers

Padding, stride and pooling

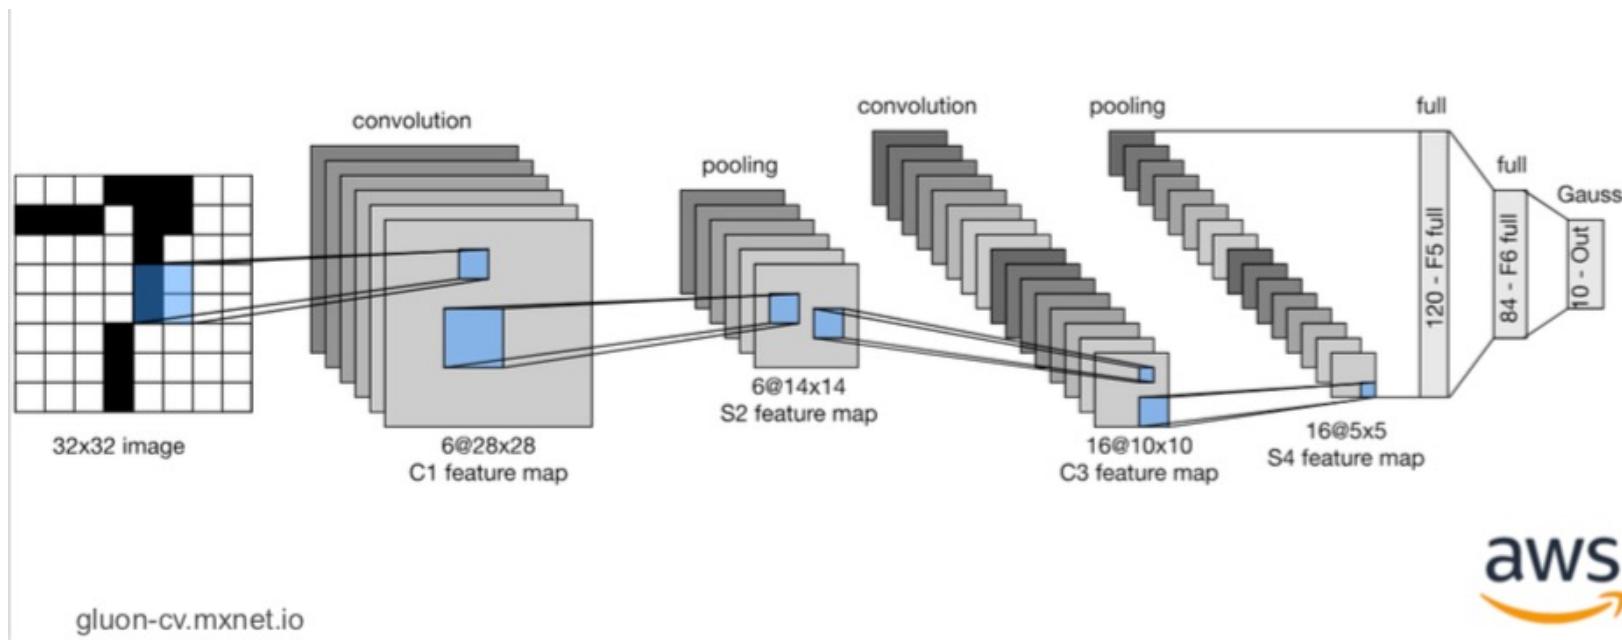

LeNet as a base architecture

# LeNet?

- The '90s .. A period many would like to forget
- But it has its good moments: in 1992, Y. LeCun and L. Bottou proposed LeNet, the first Convolutional Neural Network
- They used it to recognize digits for the U.S. post
- By lack of computational power and big datasets, the model didn't beat state of art.
- But still, these concepts are at the core of basically all modern deep learning.
- **It is simple but powerful.**

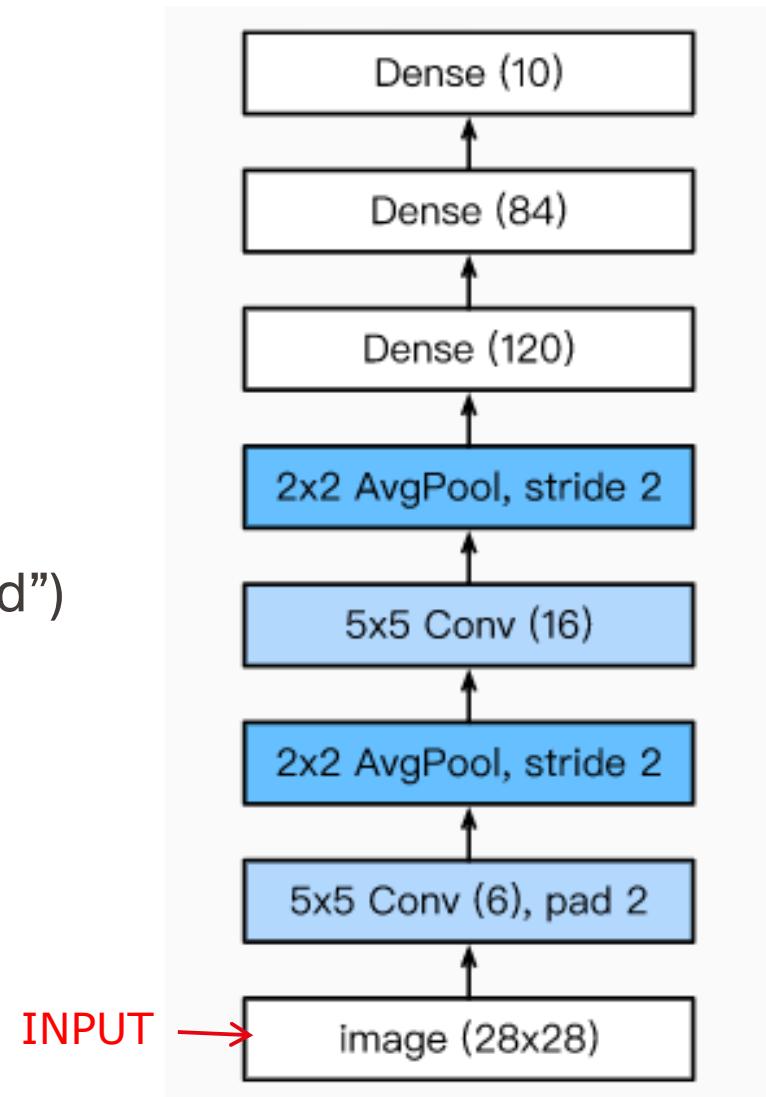

- 2 convolutional layers,  $5 \times 5$  filters >> neurons give image-like activation maps
- 2 average pooling layers >> reduce resolution of the maps
- Sigmoid nonlinearities >> no ReLUs back in the day
- 2 fully connected layers >> all the image gets summarized in a neuron, 120 times
- 10 output classes (10 digits) >> final output

- 2 convolutional layers,  $5 \times 5$  filters
- 2 average pooling layers
- Sigmoid nonlinearities
- 2 dense layers (same as “fully connected”)
- 10 output classes (10 digits)

000000000000
